Rocephin IV

ceftriaxone sodium/Roche

Before prescribing, please consult complete product information, a summary of which follows:

INDICATIONS AND USAGE: Rocephin is indicated for the treatment of the following infections when caused by susceptible organisms:

LOWER RESPIRATORY TRACT INFECTIONS caused by *Strep. pneumoniae, Streptococcus* species (excluding enterococci), *Staph. aureus, H. influenzae, H. parainfluenzae, Klebsiella* species (including *K. pneumoniae*), *E. coli, E. aerogenes, Proteus mirabilis* and *Serratia marcescens*.

SKIN AND SKIN STRUCTURE INFECTIONS caused by *Staph. aureus, Staph. epidermidis, Streptococcus* species (excluding enterococci), *E. cloacae, Klebsiella* species (including *K. pneumoniae*), *Proteus mirabilis* and *Pseudomonas aeruginosa*.

URINARY TRACT INFECTIONS (complicated and uncomplicated) caused by *E. coli, Proteus mirabilis, Proteus vulgaris, M. morganii* and *Klebsiella* species (including *K. pneumoniae*).

UNCOMPLICATED GONORRHEA (cervical/urethral and rectal) caused by *Neisseria gonorrhoeae*, including both penicillinase and nonpenicillinase producing strains.

PELVIC INFLAMMATORY DISEASE caused by *N. gonorrhoeae*.

BACTERIAL SEPTICEMIA caused by *Staph. aureus, Strep. pneumoniae, E. coli, H. influenzae* and *K. pneumoniae*.

BONE AND JOINT INFECTIONS caused by *Staph. aureus, Strep. pneumoniae, Streptococcus* species (excluding enterococci), *E. coli, P. mirabilis, K. pneumoniae* and *Enterobacter* species.

INTRA-ABDOMINAL INFECTIONS caused by *E. coli* and *K. pneumoniae*.

MENINGITIS caused by *H. influenzae, N. meningitidis* and *Strep. pneumoniae*. Ceftriaxone has also been used successfully in a limited number of cases of meningitis and shunt infections caused by *Staph. epidermidis* and *E. coli*.

SURGICAL PROPHYLAXIS: Preoperative administration of a single 1 gm dose may reduce incidence of postoperative infections in patients undergoing surgical procedures classified as contaminated or potentially contaminated (*e.g.*, vaginal or abdominal hysterectomy) and in those for whom infection at the operative site presents serious risk (*e.g.*, during coronary artery bypass surgery).

Although ceftriaxone has been shown to have been as effective as cefazolin in the prevention of infection following coronary artery bypass surgery, no placebo-controlled trials have been conducted to evaluate any cephalosporin antibiotic in the prevention of infection following coronary artery bypass surgery. When administered before indicated surgical procedures, a single 1 gm dose provides protection from most infections due to susceptible organisms for duration of procedure.

SUSCEPTIBILITY TESTING: Before instituting treatment with Rocephin, appropriate specimens should be obtained for isolation of the causative organism and for determination of its susceptibility to the drug. Therapy may be instituted prior to obtaining results of susceptibility testing.

CONTRAINDICATIONS: Rocephin is contraindicated in patients with known allergy to the cephalosporin class of antibiotics.

WARNINGS: BEFORE THERAPY WITH ROCEPHIN IS INSTITUTED, CAREFUL INQUIRY SHOULD BE MADE TO DETERMINE WHETHER THE PATIENT HAS HAD PREVIOUS HYPERSENSITIVITY REACTIONS TO CEPHALOSPORINS, PENICILLINS OR OTHER DRUGS. THIS PRODUCT SHOULD BE GIVEN CAUTIOUSLY TO PENICILLIN-SENSITIVE PATIENTS. ANTIBIOTICS SHOULD BE ADMINISTERED WITH CAUTION TO ANY PATIENT WHO HAS DEMONSTRATED SOME FORM OF ALLERGY, PARTICULARLY TO DRUGS. SERIOUS ACUTE HYPERSENSITIVITY REACTIONS MAY REQUIRE THE USE OF SUBCUTANEOUS EPINEPHRINE AND OTHER EMERGENCY MEASURES.

Pseudomembranous colitis has been reported with the use of cephalosporins (and other broad-spectrum antibiotics); therefore, it is important to consider its diagnosis in patients who develop diarrhea in association with antibiotic use.

Treatment with broad-spectrum antibiotics alters the normal flora of the colon and may permit overgrowth of clostridia. Studies indicate a toxin produced by *Clostridium difficile* is one primary cause of antibiotic-associated colitis. Cholestyramine and colestipol resins have been shown to bind to the toxin *in vitro*.

Mild cases of colitis respond to drug discontinuance alone. Moderate to severe cases should be managed with fluid, electrolyte and protein supplementation as indicated.

When the colitis is not relieved by drug discontinuance or when it is severe, oral vancomycin is the treatment of choice for antibiotic-associated pseudomembranous colitis produced by *C. difficile*. Other causes of colitis should also be considered.

Rarely, shadows suggesting sludge have been detected by sonograms of the gallbladder in asymptomatic and symptomatic patients. This appears to be reversible on discontinuation of therapy. In a few symptomatic patients receiving higher than usual doses, who underwent surgery, sludge containing traces of ceftriaxone was recovered from surgical specimens. Discontinue therapy in patients who develop signs or symptoms suggestive of gallbladder disease; consider conservative management.

PRECAUTIONS: *GENERAL*: Although transient elevations of BUN and serum creatinine have been observed, at the recommended dosages, the nephrotoxic potential of Rocephin is similar to that of other cephalosporins.

Ceftriaxone is excreted via both biliary and renal excretion (see Clinical Pharmacology). Therefore, patients with renal failure normally require no adjustment in dosage when usual doses of Rocephin are administered, but concentrations of drug in the serum should be monitored periodically. If evidence of accumulation exists, dosage should be decreased accordingly.

Dosage adjustments should not be necessary in patients with hepatic dysfunction; however, in patients with both hepatic dysfunction and significant renal disease, Rocephin dosage should not exceed 2 gm daily without close monitoring of serum concentrations.

Alterations in prothrombin times have occurred rarely in patients treated with Rocephin. Patients with impaired vitamin K synthesis or low vitamin K stores (*e.g.*, chronic hepatic disease and malnutrition) may require monitoring of prothrombin time during Rocephin treatment. Vitamin K administration (10 mg weekly) may be necessary if the prothrombin time is prolonged before or during therapy.

Prolonged use of Rocephin may result in overgrowth of nonsusceptible organisms. Careful observation of the patient is essential. If superinfection occurs during therapy, appropriate measures should be taken.

Rocephin should be prescribed with caution in individuals with a history of gastrointestinal disease, especially colitis.

CARCINOGENESIS, MUTAGENESIS, IMPAIRMENT OF FERTILITY: Carcinogenesis: Considering the maximum duration of treatment and the class of the compound, carcinogenicity studies with ceftriaxone in animals have not been performed. The maximum

[illegible] dies was six months.

Mutagenesis: [illegible] xicology tests included the Ames test, a micronucleus test and a test for chromos[illegible] errations in human lymphocytes cultured *in vitro* with ceftriaxone. Ceftriaxone showed no potential for mutagenic activity in these studies.

Impairment of Fertility: Ceftriaxone produced no impairment of fertility when given intravenously to rats at daily doses up to 586 mg/kg/day, approximately 20 times the recommended clinical dose of 2 gm/day.

PREGNANCY: Teratogenic Effects: Pregnancy Category B. Reproductive studies have been performed in mice and rats at doses up to 20 times the usual human dose and have no evidence of embryotoxicity, fetotoxicity or teratogenicity. In primates, no embryotoxicity or teratogenicity was demonstrated at a dose approximately three times the human dose. There are, however, no adequate and well-controlled studies in pregnant women. Because animal reproductive studies are not always predictive of human response, this drug should be used during pregnancy only if clearly needed.

Nonteratogenic Effects: In rats, in the Segment I (fertility and general reproduction) and Segment III (perinatal and postnatal) studies with intravenously administered ceftriaxone, no adverse effects were noted on various reproductive parameters during gestation and lactation, including postnatal growth, functional behavior and reproductive ability of the offspring, at doses of 586 mg/kg/day or less.

NURSING MOTHERS: Low concentrations of ceftriaxone are excreted in human milk. Caution should be exercised when Rocephin is administered to a nursing woman.

PEDIATRIC USE: Safety and effectiveness of Rocephin in neonates, infants and children have been established for the dosages described in the Dosage and Administration section. *In vitro* studies have shown ceftriaxone, like some other cephalosporins, can displace bilirubin from serum albumin. Exercise caution before administration to hyperbilirubinemic neonates, especially prematures.

ADVERSE REACTIONS: Rocephin is generally well tolerated. In clinical trials, the following adverse reactions, which were considered to be related to Rocephin therapy or of uncertain etiology, were observed:

LOCAL REACTIONS—pain, induration or tenderness at the site of injection (1%). Less frequently reported (less than 1%) was phlebitis after I.V. administration.

HYPERSENSITIVITY—rash (1.7%). Less frequently reported (less than 1%) were pruritus, fever or chills.

HEMATOLOGIC—eosinophilia (6%), thrombocytosis (5.1%) and leukopenia (2.1%). Less frequently reported (less than 1%) were anemia, neutropenia, lymphopenia, thrombocytopenia and prolongation of the prothrombin time.

GASTROINTESTINAL—diarrhea (2.7%). Less frequently reported (less than 1%) were nausea or vomiting, and dysgeusia.

HEPATIC—elevations of SGOT (3.1%) or SGPT (3.3%). Less frequently reported (less than 1%) were elevations of alkaline phosphatase and bilirubin.

RENAL—elevations of the BUN (1.2%). Less frequently reported (less than 1%) were elevations of creatinine and the presence of casts in the urine.

CENTRAL NERVOUS SYSTEM—headache or dizziness were reported occasionally (less than 1%).

GENITOURINARY—moniliasis or vaginitis were reported occasionally (less than 1%).

MISCELLANEOUS—diaphoresis and flushing were reported occasionally (less than 1%).

Other rarely observed adverse reactions (less than 0.1%) include leukocytosis, lymphocytosis, monocytosis, basophilia, a decrease in the prothrombin time, jaundice, gallbladder sludge, glycosuria, hematuria, anaphylaxis, bronchospasm, serum sickness, abdominal pain, colitis, flatulence, dyspepsia, palpitations and epistaxis.

DOSAGE AND ADMINISTRATION: Rocephin may be administered intravenously or intramuscularly. The usual adult daily dose is 1 to 2 gm given once a day (or in equally divided doses twice a day) depending on the type and severity of the infection. The total daily dose should not exceed 4 grams.

For the treatment of serious miscellaneous infections in children, other than meningitis, the recommended total daily dose is 50 to 75 mg/kg (not to exceed 2 grams), given in divided doses every 12 hours.

Generally, Rocephin therapy should be continued for at least two days after the signs and symptoms of infection have disappeared. The usual duration is 4 to 14 days; in complicated infections longer therapy may be required.

In the treatment of meningitis, a daily dose of 100 mg/kg (not to exceed 4 grams), given in divided doses every 12 hours, should be administered with or without a loading dose of 75 mg/kg.

For the treatment of uncomplicated gonococcal infections, a single intramuscular dose of 250 mg is recommended.

For preoperative use (surgical prophylaxis), a single dose of 1 gm administered 1/2 to 2 hours before surgery is recommended.

When treating infections caused by *Streptococcus pyogenes*, therapy should be continued for at least ten days.

No dosage adjustment is necessary for patients with impairment of renal or hepatic function; however, blood levels should be monitored in patients with severe renal impairment (*e.g.*, dialysis patients) and in patients with both renal and hepatic dysfunctions.

HOW SUPPLIED: Rocephin (ceftriaxone sodium/Roche) is supplied as a sterile crystalline powder in glass vials and piggyback bottles. The following packages are available:

Vials containing 250 mg, 500 mg, 1 gm or 2 gm equivalent of ceftriaxone; piggyback bottles containing 1 gm or 2 gm equivalent of ceftriaxone; bulk pharmacy containers containing 10 gm equivalent of ceftriaxone (NOT FOR DIRECT ADMINISTRATION).

Also supplied as a sterile crystalline powder as follows:

ADD-Vantage Vials** containing 1 gm or 2 gm equivalent of ceftriaxone.

Also supplied premixed as a frozen iso-osmotic, sterile, nonpyrogenic solution of ceftriaxone sodium in 50 mL single dose plastic containers,† as follows:

1 gm equivalent of ceftriaxone, iso-osmotic with approximately 1.9 gm dextrose hydrous, USP added.

2 gm equivalent of ceftriaxone, iso-osmotic with approximately 1.2 gm dextrose hydrous, USP added.

NOTE: Rocephin in the frozen state should not be stored above -20°C.

VICE CHAIRMAN OF SURGERY
BOSTON, MASSACHUSETTS

- Administrate Growing Surgical Department
- Serve as Chief of Academic Affairs
- Serve as Chief of General Surgery
- Faculty Appointment with Prestigious Medical School
- Growing Clinical Practice

Candidate: We seek a nationally prominent surgeon, preferably a surgical oncologist, to become Chief of Surgery at a 350-bed Boston hospital and Vice Chairman of the Department with the medical school. Candidate will be brought in at the Associate Professor range and needs commensurate academic credentials.

Location: 80% of time will be spent in 350-bed hospital, with 20% of time at medical school complex. Central Boston location allows for urban or suburban lifestyle.

Compensation: Very attractive, with all benefits plus an additional incentive package based on surgical productivity.

Application: All inquiries will be held in the strictest of confidence. Please contact Daniel Stern, President:

Daniel Stern and Associates
The Medical Center East, Suite 240
211 North Whitfield Street
Pittsburgh, Pennsylvania 15206

800-438-2476 / FAX 412-363-6032

NAPR
Member of
National Association of
Physician Recruiters

PARTNERS PRACTICING GOOD MEDICINE.

Bring your outstanding surgical skills to the Southern California Permanente Medical Group and experience the freedom to focus on patient work. Not paperwork.

We are an HMO multispecialty group practice — a partnership composed of and managed by SCPMG physicians.

Opportunities exist for board eligible/certified **Surgeons** with a combined practice of Peripheral Vascular and General Surgery.

Consider the advantages: the finest equipment and latest technology; the availability of consultations with other physicians of distinction; and a broad network of exceptional support personnel backed by the resources of one of the nation's leading HMO's.

Our compensation is competitive and benefits are outstanding. They include: professional liability, medical and dental coverage, vacation and sick leave, continuing education, life insurance and retirement plans. **After two years full-time employment, physicians are eligible to be considered for partnership.**

For a physician application, please call (818) 405-3224 or send your curriculum vitae to: Physician Recruitment, Dept. 78E8, Walnut Center, Pasadena, CA 91188-8854.

Equal Opportunity Employer M/F/H

KAISER PERMANENTE
Good People. Good Medicine.

vicodin®

(hydrocodone bitartrate 5 mg [Warning: May be habit forming] and acetaminophen 500 mg)

INDICATIONS AND USAGE: For the relief of moderate to moderately severe pain.
CONTRAINDICATIONS: Hypersensitivity to acetaminophen or hydrocodone.
WARNINGS:
Allergic-Type Reaction: VICODIN contains sodium metabisulfite, a sulfite that may cause allergic-type reactions including anaphylactic symptoms and life-threatening or less severe asthmatic episodes in certain susceptible people. The overall prevalence of sulfite sensitivity in the general population is unknown and probably low. Sulfite sensitivity is seen more frequently in asthmatic than non-asthmatic people.
Respiratory Depression: At high doses or in sensitive patients, hydrocodone may produce dose-related respiratory depression by acting directly on brain stem respiratory centers. Hydrocodone also affects centers that control respiratory rhythm, and may produce irregular and periodic breathing. If significant respiratory depression occurs, it may be antagonized by the use of naloxone hydrochloride. (see ADVERSE REACTIONS: Respiratory Depression).
Head Injury and Increased Intracranial Pressure: The respiratory depressant effects of narcotics and their capacity to elevate cerebrospinal fluid pressure may be markedly exaggerated in the presence of head injury, other intracranial lesions or a preexisting increase in intracranial pressure. Furthermore, narcotics produce adverse reactions which may obscure the clinical course of patients with head injuries.
Acute Abdominal Conditions: The administration of narcotics may obscure the diagnosis or clinical course of patients with acute abdominal conditions.
PRECAUTIONS:
Special Risk Patients: As with any narcotic analgesic agent, VICODIN should be used with caution in elderly or debilitated patients and those with severe impairment of hepatic or renal function, hypothyroidism, Addison's disease, prostatic hypertrophy or urethral stricture. The usual precautions should be observed and the possibility of respiratory depression should be kept in mind.
Information for Patients: VICODIN, like all narcotics, may impair the mental and/or physical abilities required for the performance of potentially hazardous tasks such as driving a car or operating machinery; patients should be cautioned accordingly.
Cough Reflex: Hydrocodone suppresses the cough reflex; as with all narcotics, caution should be exercised when VICODIN is used postoperatively and in patients with pulmonary disease.
Drug Interactions: Patients receiving other narcotic analgesics, antipsychotics, antianxiety agents, or other CNS depressants (including alcohol) concomitantly with VICODIN may exhibit an additive CNS depression. When combined therapy is contemplated, the dose of one or both agents should be reduced. The use of MAO inhibitors or tricyclic antidepressants with hydrocodone preparations may increase the effect of either the antidepressant or hydrocodone. The concurrent use of anticholinergics with hydrocodone may produce paralytic ileus.
Usage in Pregnancy: Pregnancy Category C. Hydrocodone has been shown to be teratogenic in hamsters when given in doses 700 times the human dose. There are no adequate and well-controlled studies in pregnant women. VICODIN should be used during pregnancy only if the potential benefit justifies the potential risk to the fetus.
Nonteratogenic effects: Babies born to mothers who have been taking opioids regularly prior to delivery will be physically dependent. The withdrawal signs include irritability and excessive crying, tremors, hyperactive reflexes, increased respiratory rate, increased stools, sneezing, yawning, vomiting, and fever. The intensity of the syndrome does not always correlate with the duration of material opioid use or dose. There is no consensus on the best method of managing withdrawal. Chlorpromazine 0.7 to 1.0 mg/kg q6h, and paregoric 2 to 4 drops/kg q4h, have been used to treat withdrawal symptoms in infants. The duration of therapy is 4 to 28 days, with the dosage decreased as tolerated.
Labor and Delivery: As with all narcotics, administration of VICODIN to the mother shortly before delivery may result in some degree of respiratory depression in the newborn, especially if higher doses are used.
Nursing Mothers: It is not known whether this drug is excreted in human milk. Because many drugs are excreted in human milk and because of the potential for serious adverse reactions in nursing infants from VICODIN, a decision should be made whether to discontinue nursing or to discontinue the drug, taking into account the importance of the drug to the mother.
Pediatric Use: Safety and effectiveness in children have not been established.
ADVERSE REACTIONS:
Central Nervous System: Sedation, drowsiness, mental clouding, lethargy, impairment of mental and physical performance, anxiety, fear, dysphoria, dizziness, psychic dependence, mood changes.
Gastrointestinal System: Nausea and vomiting may occur; they are more frequent in ambulatory than in recumbent patients. The antiemetic phenothiazines are useful in suppressing these effects; however, some phenothiazine derivatives seem to be antianalgesic and to increase the amount of narcotic required to produce pain relief, while other phenothiazines reduce the amount of narcotic required to produce a given level of analgesia. Prolonged administration of VICODIN may produce constipation.
Genitourinary System: Ureteral spasm, spasm of vesical sphincters and urinary retention have been reported.
Respiratory Depression: (See WARNINGS.)
DOSAGE AND ADMINISTRATION: Dosage should be adjusted according to the severity of the pain and the response of the patient. However, tolerance to hydrocodone can develop with continued use and the incidence of untoward effects is dose related.
The usual adult dosage is one or two tablets every four to six hours as needed for pain. The total 24 hour dose should not exceed 8 tablets.

PAPERS READ BEFORE THE ANNUAL MEETING OF THE SOCIETY OF SURGICAL ONCOLOGY, NEW ORLEANS, MAY 22 TO MAY 25, 1988—Part I

The Prognostic Significance of Lymph Node Metastases After Preoperative Chemotherapy for Locally Advanced Breast Cancer 21
David R. McCready, MD; Gabriel N. Hortobagyi, MD; Shu W. Kau, RN; Terry L. Smith, MS; Aman U. Buzdar, MD; Charles M. Balch, MD, Houston
- The number of lymph nodes with metastatic cancer had more prognostic value than other factors.

A Comparison of Palpable and Nonpalpable Breast Cancers 26
Timothy J. Pagana, MD; Willem J. Lubbe, MD; Sheldon M. Schwartz, MD; Gene D. Sprechini, PhD, Williamsport, Pa
- Obviously, nonpalpable breast cancers were smaller and more frequently noninvasive and less frequently had metastasized to lymph nodes.

Nonpalpable In Situ Ductal Carcinoma of the Breast: Predictors of Multicentricity and Microinvasion and Implications for Treatment 29
Gordon F. Schwartz, MD; Arthur S. Patchefsky, MD; Sidney D. Finklestein, MD; Sae H. Sohn, MD; Anthony Prestipino, MD; Stephen A. Feig, MD; Jodi S. Singer, MD, Philadelphia
- Ductal carcinoma in situ as an incidental finding may be treated by excision alone.

Breast Carcinoma In Situ 33
David W. Kinne, MD; Jeanne A. Petrek, MD; Michael P. Osborne, MD; Alfred A. Fracchia, MD; Angelo A. DePalo, MD; Paul Peter Rosen, MD, New York
- Axillary dissection is not indicated for in situ breast cancer.

Implications of Accurate Pathologic Margins in the Treatment of Primary Breast Cancer 37
Thomas G. Frazier, MD, Bryn Mawr, Pa; Randolph W. Y. Wong, MD, Philadelphia; David Rose, MD, Bryn Mawr, Pa
- Patients with clear or close margins after segmental resection of breast cancer were found to have residual tumor with subsequent reexcision.

Lability of Steroid Hormone Receptors Following Devascularization of Breast Tumors 39
Lee M. Ellis, MD, Gainesville, Fla; James L. Wittliff, PhD, Louisville; Michael S. Bryant, MD, Harry S. Sitren, PhD, Gainesville, Fla; William E. Hogancamp, Louisville; Wiley W. Souba, MD, ScD, Kirby I. Bland, MD, Gainesville, Fla
- Thirty minutes of tissue ischemia before processing resulted in a decrease in estrogen and androgen receptors.

Cancer Centers—Origins and Purpose: The James Ewing Lecture 43
William W. Shingleton, MD, Durham, NC
- Comprehensive cancer centers have been important, but continuous evaluation of their effectiveness is necessary.

Results of Surgical Excision of One to 13 Hepatic Metastases in 98 Consecutive Patients 46
John P. Minton, MD, PhD; Walter B. Hamilton; Armando Sardi, MD; Carol Nieroda, MD; Brenda Sickle-Santanello, MD; Patrick J. O'Dwyer, MD, Columbus, Ohio
- Resection of multiple liver metastases by local removal using electrocautery was associated with prolonged survival in a number of patients.

Experimental Liver Metastasis: Implications of Clonal Proclivity and Organ Specificity 49
T. S. Ravikumar, MD; John D'Emilia, MD; Celia Cocchiaro; Barbara Wolf, MD; Vincent King; Glenn Steele, Jr, MD, PhD, Boston
- Spontaneous metastases to lung and liver were established in this animal model.

The **ARCHIVES OF SURGERY** (ISSN 0004-0010) is published monthly by the American Medical Association, 535 N Dearborn St, Chicago, IL 60610, and is an official publication of the Association. Second-class postage paid at Chicago, IL 60610 and at additional mailing office.

SUBSCRIPTION RATES—The subscription rates for the ARCHIVES OF SURGERY are as follows: $50 for one year, $85 for two years in the United States and US possessions; all other countries, one year, $60; two years, $105 for surface delivery. (For expedited air delivery to most countries, add $15 surcharge for one-year subscription, $30 for two years.) Rates for subscriptions for delivery to Japan or South Korea are available through exclusive agents—contact the publisher. ***Special rates for residents and medical students in the United States and US possessions are available.*** Address inquiries to the American Medical Association, Circulation and Fulfillment Division, 535 N Dearborn St, Chicago, IL 60610. Phone: (312)280-7168.

CHANGE OF ADDRESS—POSTMASTER, send all address changes for the ARCHIVES OF SURGERY to Caryl L. Wertheimer, Director of Fulfillment, 535 N Dearborn St, Chicago, IL 60610. Notification of address change must be made at least six weeks in advance, include both old and new addresses, a recent mailing label, and your new zip code.

ADVERTISING PRINCIPLES: Each advertisement in this issue has been reviewed and complies with the principles governing advertising in AMA scientific publications. A copy of these principles is available on request. The appearance of advertising in AMA publications is not an AMA guarantee or endorsement of the product or the claims made for the product by the manufacturer.

CONTENTS—Continued

Intra-abdominal Recurrence of Colorectal Cancer Detected by Radioimmunoguided Surgery (RIGS System) 55
Armando Sardi, MD; Mark Workman; Cathy Mojzisik, RN, MS; George Hinkle, RPh; Carol Nieroda, MD; Edward W. Martin, Jr, MD, Columbus, Ohio
- In some patients undergoing second-look operations, recurrent tumor was located only by the technique of radiolabeled monoclonal antibodies.

Rationale for Aggressive Colonoscopy in Patients With Colorectal Neoplasia 63
Kumar S. Dasmahapatra, MD, Kevin Lopyan, MD, Newark, NJ
- Metachronous colon cancers were found by colonoscopy as late as 60 months after an initial cancer resection.

Prospective Phase I Trial of Conservative Management of Low Rectal Lesions 67
David R. McCready, MD; David M. Ota, MD; Tyvin A. Rich, MD; Diva Thielvoldt, RN; J. Milburn Jessup, MD, Houston
- In selected patients with low rectal cancer, local excision and radiotherapy was done with early, good results.

Staging Renal Carcinoma: What Is Sufficient? 71
Mark A. Benson, MD; John R. Haaga, MD; Martin I. Resnick, MD, Cleveland
- Computed tomography is the principal technique for overall staging of renal cell carcinoma.

Photodynamic Therapy for Esophageal Tumors 74
James S. McCaughan, Jr, MD; Thomas A. Nims, MD; Jerry T. Guy, MD; William J. Hicks, MD; Thomas E. Williams Jr, MD; Leslie R. Laufman, MD, Columbus, Ohio
- Improvement in ability to swallow was provided in a number of patients.

Effect of Timing of Lymphokine Presentation on Generation of Cytotoxic T Lymphocytes 81
Monica M. Stringfellow, MD; Richard E. Wilson, MD; Steven J. Burakoff, MD; Steven H. Herrmann, MD, Boston
- Both interleukin 1 and interleukin 6 are required for optimal generation of cytotoxic T lymphocytes.

Natural Killer Sensitivity of Colorectal Carcinoma Targets: Correlation With Degree of Differentiation 89
Darius J. Bägli, MD, CM; Glenn D. Steele, Jr, MD, PhD; Teresa Barlozzari, PhD, Boston
- Poorly differentiated colorectal cancer cells were susceptible to natural killer cell lysis.

Cachectin Activity in the Serum of Cachectic, Tumor-Bearing Rats 94
Mark C. Stovroff, MD; Douglas L. Fraker, MD; Jeffrey A. Norton, MD, Bethesda, Md
- Serum cachectic activity correlated with tumor burden, and the levels became undetectable following tumor resection.

The Flip Side of Tumor Immunity 102
Richmond T. Prehn, MD, Liisa M. Prehn, MD, Seattle
- Immunosuppression may be as likely to have a therapeutic effect as immunoaugmentation.

Recombinant Human Tumor Necrosis Factor Alone and With Chemotherapeutic Agents: Effect on Nude Mouse–Supported Human Bladder Cancer Heterografts 107
Anurag K. Das, MD; Philip J. Walther, MD, PhD; Niall J. Buckley, MD; Susan H. M. Poulton, Durham, NC
- Synergism between recombinant human tumor necrosis factor and chemotherapeutic agents was found only with etoposide.

Squamous Cell Carcinoma Arising in Previously Burned or Irradiated Skin 115
Michael J. Edwards, MD; Rose M. Hirsch, MD; J. Ralph Broadwater, MD; David T. Netscher, MD; Frederick C. Ames, MD, Houston
- Chronic ulceration in scar tissue should suggest this diagnosis.

Is Limb-Sparing Surgery Applicable to Neurogenic Sarcomas of the Extremities? 118
John S. Bolton, MD; Jean-Nicolas Vauthey, MD; Gist H. Farr, Jr, MD; Edward I. Sauter, MD; John C. Bowen III, MD; David G. Kline, MD, New Orleans
- Patients with high-grade neurogenic sarcomas of the extremities have a high risk of local recurrence after limb-sparing operative treatment.

Patterns of Recurrence After Resection of Osteosarcoma of the Extremity: Strategies for Treatment of Metastases 122
James F. Huth, MD, Frederick R. Eilber, MD, Los Angeles
- The prognosis is particularly bad with metastases to the lung and other sites.

Clinical Experience With Regional Pancreatectomy for Adenocarcinoma of the Pancreas 127
William F. Sindelar, MD, PhD, Bethesda, Md
- Regional pancreatectomy with en bloc pancreatectomy and removal of regional nodes, duodenum, gastric antrum, and intrapancreatic portal vein produced little survival benefit for most patients.

OVER A CENTURY AGO,

a thousand visionary physicians across the nation bestowed a commemorative stone carving to the Washington Monument. This patriotic display symbolized their unrelenting devotion to a new republic founded on freedoms—including the freedom to practice medicine for the best possible health of all its people. *Today your help is needed to restore this symbol of our profession.*

Because the commemorative stone has suffered from severe erosion and defacement, the American Medical Association is launching a campaign to raise money from physicians to restore this symbol of medicine for the National Park Service. Every contribution made to this effort will serve as a statement of each physician's personal affirmation and commitment to health and medicine in America.

Please take part in rededicating the commemorative stone as a shining example of the strength of medicine in a free and strong society. Contributors who donate $100 or more will receive a memorial replica of the carving as a token of appreciation. Send your tax deductible contribution for this timeless symbol today. Thank you.

Yes, I want to affirm my commitment to health and medicine in America. Please accept my contribution for:

_____ Other
_____ $100
_____ $50
_____ $25

Please make checks payable to: AMA Stone/National Park Service. Mail your payment with this form to:

AMA Stone/National Park Service

All donations are tax deductible. All contributions will be publicly recognized in an unveiling ceremony for the new stone when it is fully restored.

Thank you for your contribution.

ETHICON test-fires every stapler at least once, so you don't have to think twice about using them.

Whether it's our reloadable disposable staplers or our disposable ones, every ETHICON* stapler is test-fired by a quality control professional. In addition, staple cartridges meet the highest standards for uniformity. Thus, whether stapler and cartridges are purchased at the same time or years apart, we guarantee both fit and function. As a result, whenever you use an ETHICON stapler, you know you are using a proven performer.

Instructions for Authors

Manuscripts are to be sent by first-class mail to the Editor, Claude H. Organ, Jr, MD Professor, Dept of Surgery, University of California–Davis, East Bay 1411 E 31st St, Oakland, CA 94602. The procedures listed must be followed carefully and all materials requested must be enclosed for prompt review and consideration for publication in the *Archives of Surgery*. Use the checklist to ensure completeness.

Manuscript Preparation.—*The original typescript and two high-quality copies* of the entire manuscript must be submitted, including copies of all illustrations, legends, tables, and references. All copy, including references, legends, and tables, must be typed double-spaced on 8½ × 11-in, heavy-duty white bond paper. Margins must be at least 1 in. If a word processor is used, do *not* use justified right margins.

Abstract.—*Submit an abstract* (135-word maximum) of the manuscript, which must include a statement of the problem, methods of study, results, and conclusions. The synopsis-abstract replaces a summary or conclusions.

Copyright.—*A copyright release* form signed by *all* authors of manuscripts, brief communications, and correspondence is required by the Copyright Revision Act of 1976. The following statement, dated and signed by all authors, may be used: **"In consideration of the American Medical Association's taking action in reviewing and editing my submission, the author(s) undersigned hereby transfers, assigns, or otherwise conveys all copyright ownership to the AMA in the event that such work is published by the AMA."**

Financial Interest.—List all affiliations with or financial involvement in any organization or entity with a direct financial interest in the subject matter or materials of the research discussed in the manuscript (eg, employment, consultancies, stock ownership). All such information will be held in confidence during the review process. Should the manuscript be accepted, the Editor will discuss with the author the extent of disclosure appropriate for publication.

References.—*References* should be listed in *consecutive numerical order* as they are cited in the text, *not alphabetically*. Once a reference is cited, all subsequent citations should be to the original number. All references must be cited in the text or tables. Unpublished data and personal communication may not be listed as references. References to journal articles should include (1) authors, (2) title, (3) journal name as abbreviated in *Index Medicus*, (4) year, (5) volume number, and (6) inclusive page numbers—in that order. References to books should include (1) authors, (2) chapter title, if any, (3) editor, if any, (4) title of book, (5) year, (6) city, and (7) publisher. Volume and edition numbers, specific pages, and name of translator should be included when appropriate. The author is responsible for the accuracy and completeness of the references and for their correct text citation.

Author Responsibility.—One author must be designated *corresponding author*, with his or her address and telephone number provided. All correspondence and copy editing are sent to this author. The corresponding author will receive an edited typescript rather than galley proofs for approval. The authors are responsible for all statements in their work, including changes made by the copy editor. Order reprints at the time the typescript is returned after editorial processing. Specify the address to which requests for reprints should be sent.

Titles.—*The title* must be *short*, specific, and clear. It cannot exceed 42 characters per line, including punctuation and spaces, and is limited to two lines. The title page should include the full names and academic affiliations of all authors. If the manuscript was presented at a meeting, indicate the name of the organization, the place, and the date on which it was read.

SI Units.—Use Système International (SI) measurements throughout the manuscript.

Illustrations.—Use only illustrations that clarify and augment the text. Submit illustrations in triplicate, unmounted and untrimmed. Do not send original artwork. Send high-contrast glossy prints (not photocopies). Figure number, name of senior author, and arrow indicating "top" should be typed on a gummed label and affixed to the back of each illustration. All lettering must be legible after reduction to column size. Artwork submitted for publication may be relettered to achieve uniformity of lettering style throughout the journal. Illustrations should preferably be in a proportion of 5 × 7 in. *Color illustrations* are accepted for publication if the editors believe that color will add significantly to the published manuscript. The ARCHIVES will pay only part of the expense of color reproduction and printing color illustrations. The author's share of the expense is $400 for up to six square finished illustratons that can be arranged on a one-page layout. Any additional illustrations or special effects will be billed to the author at cost. Positive color transparencies (35-mm preferred) must be submitted for an evaluation. Do not send color prints unless accompanied by original transparencies.

CHECKLIST FOR AUTHORS

Send:

- Three copies of manuscript.
- Three copies of synopsis-abstract.
- Three copies of attached photographs, legends, tables, and/or illustrations clearly marked as described in the instructions.
- A copyright release statement signed by *all* authors.
- The address and telephone number of the designated corresponding author.
- Send to Claude H. Organ, Jr, MD
  Archives of Surgery
  Professor, Dept of Surgery
  University of California–Davis, East Bay
  1411 E 31st St
  Oakland, CA 94602
- Use sufficient postage.

Legends.—*Legends* must be typed double-spaced, beginning on a separate sheet of paper. Length is limited to a maximum of 40 words.

Tables.—Each table must be typed double-spaced, including all headings, on a separate sheet of 8½ × 11-in paper. Do not use larger-size paper. If a table must be continued, use a second sheet and repeat all heads and stubs. Each table must have a title.

Manuscript Acceptance.—Manuscripts are received with the understanding that they *are not* under simultaneous consideration by another publication. Accepted manuscripts become the permanent property of the ARCHIVES and may not be published elsewhere without permission from the publisher (AMA).

OTHER INFORMATION

Brief Clinical Notes.—The ARCHIVES welcomes the submission of Brief Clinical Notes for review. These are generally reports of cases that provide a new or unique contribution and are to consist of no more than 400 words, two references, and one illustration. The synopsis-abstract may not exceed 80 words.

Correspondence and Brief Communications.—The Editor is pleased to receive letters that pertain to material published in the ARCHIVES as well as brief communications concerning other matters of interest to our readers. An interesting case may be published as a brief communication. Such contributions should be 250 words or less, typewritten, double-spaced without an abstract, and clearly marked "for publication." No more than two references are permitted and illustrations or tables are acceptable only when essential to the message.

News and Announcements.—Brief notices may be submitted of meetings, seminars, or symposiums that are of interest to surgeons.

Acknowledgments.—Illustrations from other publications must be acknowledged. Include the following when applicable: authors, title of article, title of journal or book, volume number, pages, month and year. The publisher's permission to reprint must be submitted to the ARCHIVES when the manuscript has been formally accepted.

Statistical Review.—Manuscripts containing statistical evaluation should include the name and affiliation of the statistical reviewer.

Informed Consent.—Manuscripts reporting the results of experimental investigations on human subjects must include a statement to the effect that informed consent was obtained after the nature of the procedure(s) had been fully explained.

Reference to Patients.—Patients should be referred to by number or, in anecdotal reports, by fictitious given names. Real names or initials must not be used in the text, tables, or illustrations.

Photographic Consents.—A letter of consent must accompany all photographs of patients in which a possibility of identification exists. It is *not* sufficient to simply cover the eyes to mask identity.

AMA Manual of Style.—This 1988 edition, formerly the *Manual for Authors & Editors*, is available from Williams & Wilkins, 428 E Preston St, Baltimore, MD 21202. Single copy price: $24.95. A shipping charge is added on all orders not prepaid. If additional ordering information is needed, or to order by telephone, call 1-800-638-0672.

If this looks to you like a goose on roller skates, you could be going blind.

No, there's nothing wrong with your vision.

But there could be something wrong with your eyes.

You could have an eye disease serious enough to blind you, and not even know it. The leading cause of blindness in adults, glaucoma, has no symptoms in early stages.

There is no cure. But there is hope.

You can stop glaucoma from advancing (and many other eye diseases from happening in the first place) by seeing an eye doctor at least every two years.

Remember, no one can save your sight but you.

GENERAL SURGEON—Excellent opportunity for Board Certified or Eligible general surgeon in large multispecialty group in Pacific Northwest. Immediate position available in 23-member surgery department in early or mid-1988. Group provides comprehensive medical care to 330,000 members of Kaiser Permanente in Oregon and Washington. Excellent salary and benefits, with opportunity to become shareholder after two years. Direct inquiry and c.v. to: Regional Medical Director, Northwest Permanente, P.C., 3600 N. Interstate Avenue, Portland, OR 97227.

FLORIDA, OKLAHOMA

General Surgery Opportunities

FLORIDA: Gainesville-based regional multi-hospital Healthcare System has immediate need for BE/BC general surgeons. Paid malpractice, salary guarantee, office space, moving expenses, others.

OKLAHOMA: BE/BC general surgeon needed to join multi-specialty group. Fee-for-service practice. Progressive, thriving, family oriented community. Excellent income potential and relocation package.

CONTROL THE ACID RISK

Unlike antacids or sucralfate, ZANTAC® Injection controls both gastric pH and gastric volume. ZANTAC 50 mg IV rapidly increases pH to 6.2 within 1½ hours and keeps it within a desirable range for up to 8 hours.[1] And ZANTAC reduces secretory volume—up to 50% after administration of a 50 mg intravenous dose.[2]

ZANTAC 50 mg IV q6-8h instead of antacids—to help reduce the risk of aspiration pneumonitis, diarrhea, or alkalosis.

- ZANTAC produces no clinically significant drug interactions with theophylline, phenytoin, or warfarin.
- ZANTAC does not affect blood levels of medications metabolized by the hepatic cytochrome P-450 enzyme system, such as propranolol, diazepam, lidocaine, meperidine, carbamazepine, or valproic acid.

Zantac® Injection

ZANTAC® Injection
(ranitidine hydrochloride)

BRIEF SUMMARY

ZANTAC® Injection Premixed
(ranitidine hydrochloride)

The following is a brief summary only. Before prescribing, see complete prescribing information in ZANTAC® Injection/ZANTAC® Injection Premixed product labeling.

INDICATIONS AND USAGE: ZANTAC® Injection and ZANTAC® Injection Premixed are indicated in some hospitalized patients with pathological hypersecretory conditions or intractable duodenal ulcers, or as an alternative to the oral dosage form for short-term use in patients who are unable to take oral medication.

CONTRAINDICATIONS: ZANTAC® Injection and ZANTAC® Injection Premixed are contraindicated for patients known to have hypersensitivity to the drug.

PRECAUTIONS: General: 1. Symptomatic response to ZANTAC® therapy does not preclude the presence of gastric malignancy.

2. Since ZANTAC is excreted primarily by the kidney, dosage should be adjusted in patients with impaired renal function (see DOSAGE AND ADMINISTRATION). Caution should be observed in patients with hepatic dysfunction since ZANTAC is metabolized in the liver.

3. In controlled studies in normal volunteers, elevations in SGPT have been observed when H_2-antagonists have been administered intravenously at greater than recommended doses for five days or longer. Therefore, it seems prudent in patients receiving IV ranitidine at doses greater than or equal to 100 mg qid for periods of five days or longer to monitor SGPT daily (from day 5) for the remainder of IV therapy.

4. Bradycardia in association with rapid administration of ZANTAC Injection has been reported rarely, usually in patients with factors predisposing to cardiac rhythm disturbances. Recommended rates of administration should not be exceeded (see DOSAGE AND ADMINISTRATION).

Laboratory Tests: False-positive tests for urine protein with Multistix® may occur during ZANTAC therapy, and therefore testing with sulfosalicylic acid is recommended.

Drug Interactions: Although ZANTAC has been reported to bind weakly to cytochrome P-450 in vitro, recommended doses of the drug do not inhibit the action of the cytochrome P-450-linked oxygenase enzymes in the liver. However, there have been isolated reports of drug interactions that suggest that ZANTAC may affect the bioavailability of certain drugs by some mechanism as yet unidentified (eg, a pH-dependent effect on absorption or a change in volume of distribution)

Carcinogenesis, Mutagenesis, Impairment of Fertility: There was no indication of tumorigenic or carcinogenic effects in lifespan studies in mice and rats at oral doses up to 2,000 mg/kg/day.

Ranitidine was not mutagenic in standard bacterial tests *(Salmonella, Escherichia coli)* for mutagenicity at concentrations up to the maximum recommended for these assays.

In a dominant lethal assay, a single oral dose of 1,000 mg/kg to male rats was without effect on the outcome of two matings per week for the next nine weeks.

Pregnancy: ***Teratogenic Effects: Pregnancy Category B:*** Reproduction studies have been performed in rats and rabbits at oral doses up to 160 times the human oral dose and have revealed no evidence of impaired fertility or harm to the fetus due to ZANTAC. There are, however, no adequate and well-controlled studies in pregnant women. Because animal reproduction studies are not always predictive of human response, this drug should be used during pregnancy only if clearly needed.

Nursing Mothers: ZANTAC is secreted in human milk. Caution should be exercised when ZANTAC is administered to a nursing mother.

Pediatric Use: Safety and effectiveness in children have not been established.

Use in Elderly Patients: Ulcer healing rates in elderly patients (65 to 82 years of age) treated with oral ZANTAC were no different from those in younger age groups. The incidence rates for adverse events and laboratory abnormalities were also not different from those seen in other age groups.

ADVERSE REACTIONS: Transient pain at the site of intramuscular injection has been reported. Transient local burning or itching has been reported with intravenous administration of ZANTAC®.

The following have been reported as events in clinical trials or in the routine management of patients treated with oral or parenteral ZANTAC. The relationship to ZANTAC therapy has been unclear in many cases. Headache, sometimes severe, seems to be related to ZANTAC administration.

Central Nervous System: Rarely, malaise, dizziness, somnolence, insomnia, and vertigo. Rare cases of reversible mental confusion, agitation, depression, and hallucinations have been reported, predominantly in severely ill elderly patients. Rare cases of reversible blurred vision suggestive of a change in accommodation have been reported.

Cardiovascular: As with other H_2-blockers, rare reports of arrhythmias such as tachycardia, bradycardia, asystole, A-V block, and premature ventricular beats.

Gastrointestinal: Constipation, diarrhea, nausea/vomiting, abdominal discomfort/pain, and rare reports of pancreatitis.

Hepatic: In normal volunteers, SGPT values were increased to at least twice the pretreatment levels in 6 of 12 subjects receiving 100 mg qid IV for seven days, and in 4 of 24 subjects receiving 50 mg qid IV for five days. With oral administration there have been occasional reports of hepatitis, hepatocellular or hepatocanalicular or mixed, with or without jaundice. These were usually reversible.

Musculoskeletal: Rare reports of arthralgias.

Hematologic: Reversible blood count changes (leukopenia, granulocytopenia, and thrombocytopenia) have occurred in a few patients. Rare cases of agranulocytosis, pancytopenia, sometimes with marrow hypoplasia, and aplastic anemia have been reported.

Endocrine: Controlled studies in animals and man have shown no stimulation of any pituitary hormone by ZANTAC and no anti androgenic activity, and cimetidine-induced gynecomastia and impotence in hypersecretory patients have resolved when ZANTAC has been substituted. However, occasional cases of gynecomastia, impotence, and loss of libido have been reported in male patients receiving ZANTAC, but the incidence did not differ from that in the general population.

Integumentary: Rash, including rare cases suggestive of mild erythema multiforme, and, rarely, alopecia.

Other: Rare cases of hypersensitivity reactions (eg, bronchospasm, fever, rash, eosinophilia), anaphylaxis, angioneurotic edema, and small increases in serum creatinine.

OVERDOSAGE: Information concerning possible overdosage and its treatment appears in the full prescribing information.

DOSAGE AND ADMINISTRATION: (See complete prescribing information in ZANTAC® Injection/ZANTAC® Injection Premixed product labeling.)

Dosage Adjustment for Patients with Impaired Renal Function: On the basis of experience with a group of subjects with severely impaired renal function treated with ZANTAC, the recommended dosage in patients with a creatinine clearance less than 50 ml/min is 50 mg every 18 to 24 hours. Should the patient's condition require, the frequency of dosing may be increased to every 12 hours or even further with caution. Hemodialysis reduces the level of circulating ranitidine. Ideally, the dosage schedule should be adjusted so that the timing of a scheduled dose coincides with the end of hemodialysis.

HOW SUPPLIED: ZANTAC® Injection, 25 mg/ml, containing phenol 0.5% as preservative, is available as follows:

NDC 0173-0362-38 2-ml single-dose vials (Tray of 10)
NDC 0173-0363-39 10-ml multi-dose vials (Singles)
NDC 0173-0363-00 40-ml Pharmacy Bulk Packages (Singles)
NDC 0173-0362-00 2-ml single-dose, prefilled, disposable syringes (Singles)

Store below 30°C (86°F). Protect from light.

ZANTAC Injection Premixed in 0.45% Sodium Chloride, 0.5 mg/ml, is available as a sterile premixed solution for IV administration in 100-ml single-dose flexible plastic containers (NDC 0173-0407-00). It contains no preservatives.

Exposure of pharmaceutical products to heat should be minimized. Avoid excessive heat. Protect from freezing. It is recommended that the product be stored at room temperature (25°C); however, brief exposure up to 40°C does not adversely affect the product.

You don't have to be an American to die of a heart attack.

You also don't have to overeat. Or consume excessive amounts of cholesterol. Or ignore high blood pressure. Or smoke. But that's what a large segment of this country's population does. And that's one reason the United States has the highest incidence of heart attack in the world. At the American Heart Association, we're trying to help Americans change the way they live. And die.

American Heart Association

This space provided as a public service.

Hail and Farewell

I thank those who have contributed so much to the *Archives of Surgery* over the past 12 years, and I salute the new Editor, Dr Claude H. Organ, Jr. It was a great privilege for me to succeed Dr Richard Warren in 1976, and the intervening years have been joyful and challenging. Responsibility for the editorial content of a major surgical publication is of greater consequence.

I am most grateful, first of all, to those who make a publication possible: the readers and the writers. The *Archives of Surgery* now is received internationally by over 75 000 readers who have consistently demonstrated their interest and support by high readership surveys and positive responses to queries about relevance and value of our printed material. The writers—authors, investigators, clinicians, and teachers—have provided a wealth of material from which to select and publish. So much that is worthwhile cannot be accommodated. So much that is important must wait for many months before it can be printed. This weighs heavily on an editor, and I appreciate the courtesy and good humor of those who must wait or go elsewhere.

The real heroes of a peer-review publication are the reviewers and members of the Editorial Board. Careful, considerate, thoughtful, and expert reviews have become a hallmark of our Editorial Board members and the many anonymous external reviewers. How many of our manuscripts—yours, mine—have been improved, clarified, and made more accurate and succinct by their considered comments? Theirs' is a labor of love for matters surgical. A monthly listing of the Editorial Board members on the masthead and a yearly listing of the names of our many other reviewers are hardly compensation for their efforts. I greatly appreciate and salute their excellent work.

The publications staff of the American Medical Association in Chicago has been an immense help—enjoyable to work with, supportive during my occasional editorial lapses, and always ensuring a quality publication. My thanks to them.

Finally, a special thanks to the *Archives of Surgery* office staff and my associates. Dr Ben Eiseman has served as Book Review Editor for many years, and his thoughtful and always entertaining reviews have made this a popular feature of the journal. Dr Hastings K. Wright served as Associate Editor during the New Haven days and was a great help in establishing our peer-review system and in taking over for me during a sabbatical and other junkets. Dr Donald L. Kaminski has been both an immense help and a scholarly addition in St Louis as Associate Editor, serving truly in a labor of love for surgery. Mrs Nancy Nyhan served superbly as editorial assistant during the New Haven years. My business managers at Yale, Joe Podgorski and Elinor Ingenito, were an immense help. My wife Rosemary provided the transition from New Haven to St Louis and made it possible to move the editorial office and get off to a fast and excellent start at St Mary's Health Center. In recent years, Kathy Illyes and Kit Hereford have served admirably as editorial assistant and associate, and I am very grateful to them. Sister Betty Brucker, FSM, and St Mary's Health Center have been most gracious in providing a home for the editorial office.

I also welcome Dr Organ to his new task. The *Archives of Surgery* will be in excellent hands, and I am most pleased to pass the pen on to him. His capabilities as a scholar, clinician, and leader will stand him in good stead as the ARCHIVES moves into a new era of scientific publication. It is most appropriate and exciting now to have new leadership. The time has come for more creative thinking and renewed vigor. I have tremendously enjoyed and benefited from my tour and will miss many aspects of the job. I do, however, look forward to recovery from "briefcase elbow" (lateral epicondyle extensor carpi radialis brevis inflammation produced by carrying a heavy briefcase filled with manuscripts through airports and parking lots). As this recovery occurs, my tennis game should subsequently improve, although some members of the Editorial Board would challenge that possibility.

I look forward now to joining all of you as readers of the *Archives of Surgery* and thank you for the wonderful experiences I have had.

ARTHUR E. BAUE, MD
St Louis

A New Editor for the ARCHIVES

The American Medical Association is proud to announce the appointment of Claude H. Organ, Jr, MD, as Editor of the *Archives of Surgery*.

The selection of Dr Organ was the result of the most exhaustive search process in recent AMA history. As is the custom, a search committee comprising several of the leading figures in the specialty was formed, with the Editor of one of the other AMA Specialty Journals—in this case, William W. McLendon, MD, of the *Archives of Pathology & Laboratory Medicine*—serving as chairman. The initial call for nominations resulted in more than 75 letters of recommendation; the initial list of candidates read like a *Who's Who* of the surgical field. The committee assiduously pared this number down to 30 active candidates. After more than a year of deliberation, letter writing, and conference calls the committee presented a list of five finalists, in order of preference, to George D. Lundberg, MD, AMA Vice-President for Scientific Information. Dr Organ's name was at the top of the list.

Claude H. Organ, Jr, was graduated cum laude from Xavier University in New Orleans and received his medical degree from Creighton University School of Medicine in Omaha in 1952. His ties to Creighton are long and strong: he went on to perform his residency there and received an MS in surgery in 1957. After a tour of duty as a lieutenant commander in the US Navy, stationed at the US Naval Hospital at Camp Pendelton, Calif, Dr Organ returned to Creighton as an instructor of surgery. He rose quickly through the academic hierarchy and in 1971 was named Professor and Chairman of the Department of Surgery and Chief Physician in Surgery at Creighton Memorial St Joseph Hospital.

In 1982, seeking a warmer climate and more time in the teaching arena, Dr Organ accepted a professorship at the University of Oklahoma, Oklahoma City, where he served until the fall of last year.

No stranger to multiple challenges, Dr Organ is beginning another professional chapter concurrent with his new editorship of the ARCHIVES. Recently he moved to Oakland, Calif, to become Professor of Surgery and Director of Surgical Residency at the University of California Davis–East Bay. This exciting and innovative new program will combine the resources of several institutions—Highland Hospital Center, Martinez Veterans Administration Center, Kaiser Oakland, Merritt Hospital, and Oakland Children's Hospital—to establish UC Davis's academic presence in the East Bay.

In addition to his notable career in academic medicine, Dr Organ recently served with distinction as Chairman of the American Board of Surgery, the first black to achieve that high honor. He is a former President of the Southwestern Surgical Congress and maintains memberships in national and international medical societies too numerous to list here.

A speaker of international renown, Dr Organ is much in demand as a lecturer and visiting professor. In May 1986 he was awarded an honorary fellowship in the Royal College of Surgeons of South Africa. He has authored more than 100 articles and book chapters, primarily in the areas of endocrinology, oncology, and surgical gastroenterology.

Perhaps Dr Organ's most important—and, for him, enjoyable—contribution to surgery has been as an educator. His skill, humor, and larger-than-life presence in the surgical theater have instructed and inspired countless surgical residents.

His appointment as Editor of the ARCHIVES provides an extraordinary opportunity to extend this role to a larger arena. The *Archives of Surgery* has the largest circulation of any surgical publication in the world—currently 73 000. The journal is received by virtually all physicians in the

Claude H. Organ, Jr, MD. New Editor, *Archives of Surgery*.

areas of general and orthopedic surgery as well as those in urology and numerous surgical subspecialties. The new Editor has an enormous task ahead of him: to address this vast, diversified audience of surgeons, to inform, to teach, and to explore all areas of interest to the specialty at large.

Dr Organ inherits a journal that ranks among the top in its field thanks to the efforts of his predecessor, Arthur E. Baue, MD. Dr Baue took the reins of the ARCHIVES in 1977 and skillfully guided the journal through some very difficult times. Over the years he has established relationships with several prominent surgical societies, watched the number of manuscript submissions steadily increase, and kept the journal on a solid foundation. Art Baue has been one of the senior statesmen of the AMA journals, and we will miss his wit and wise counsel.

In Claude Organ the ARCHIVES has found a surgeon of enormous worldwide stature to assume this important editorship. The catalogue of Dr Organ's professional achievements, although impeccable and impressive, is only part of the reason for his appointment. Meeting him confirms what his curriculum vitae only suggests: this is an extraordinary person. That fact quickly becomes apparent to colleagues, students, and staff members who work with him. It became obvious to the search committee that ultimately recommended him, based on the glowing endorsements and lavish praise from his surgical colleagues around the world, and to the AMA staff in our initial contacts with him as he sets up his base in Oakland. Claude Organ's life and career have been a model of excellence for persons of all races and nationalities to admire and emulate. The ARCHIVES is proud to welcome him to the circle of editors and looks forward to his leadership.

MICHAEL D. SPRINGER
Managing Editor and Director
AMA Specialty Journals
Chicago

Inaugural Editorial

Each successive generation of doctors stands, as it were, upon the shoulders of its predecessors.

F. M. R. Walske (1888)

The honor of becoming the seventh Editor of the American Medical Association's *Archives of Surgery* becomes immediately muted by the intensity of the task ahead. I am pleased and flattered to follow in the footsteps of previous editors Dean Lewis (1937 to 1940), Waltman Walters (1941 to 1942, 1946 to 1961), Lester Dragstedt (1943 to 1945), J. Garrett Allen (1962 to 1969), Richard Warren (1970 to 1976) and Arthur Baue (1977 to 1988). These illustrious predecessors, highly respected by their peers, have established a tradition for the ARCHIVES for almost half a century of American surgery.

During the last 12 years, Arthur E. Baue has performed a superb job of reestablishing the ARCHIVES as one of the foremost journals in this hemisphere and guided its destiny during a period of unparalleled changes in American surgery. These years have been characterized by an explosion of information, innumerable diagnostic and therapeutic additions, and geometric technical and communication advances. Art Baue has dared to publish controversial articles while applying his unique clinical and scientific research expertise to the contents of this journal. The vignettes he has added to the ARCHIVES have made it informative and readable for a wider variety of academic and community surgeons whose composition is constantly undergoing change. This is confirmed by the 62% increase in average total circulation from 44 523 in 1983 to 71 673 in 1987. Baue's editorial, "Peer and/or Peerless Review"[1] is a thoughtful classic that editors and editorial board members would be wise to read and keep in their reprint file.

We express our appreciation to Dr Baue for his seminal contributions. He has consented to remain as the senior consulting editor of the ARCHIVES. In addition, appreciation is extended to Dr D. L. Kaminski as associate editor; Mrs Katherine Illyes, editorial assistant; Katherine Hereford, secretary; Dr George D. Lundberg; Michael D. Springer; editorial board members who served under Dr Baue during his 12-year tenure; and the AMA Publications Staff.

The AMA established the *Archives of Internal Medicine* in 1910, and after considerable discussion approved the publication of the *American Archives of Surgery* in 1911. Assuming it would result in serious damage to their publications, the editors of the *Annals of Surgery* (L. S. Pilcher) and *Surgery, Gynecology and Obstetrics* (F. H. Martin) protested the publication of the ARCHIVES. The AMA Board of Trustees, however, decided to proceed with this publication.

The first issue of the *Archives of Surgery* was published in July 1920. The editorial board included Drs Dean Lewis,

Dean Lewis

Lester Dragstedt

Richard Warren

Waltman Walters

J. Garrett Allen

Arthur Baue

Evarts Graham, Hugh Cabot, Thomas Cullen, William Darrach, and William J. Mayo. In the inaugural editorial William J. Mayo stated,

> It is the hope of the editorial board that the *Archives of Surgery* may be one of the organs of expression in this growing field of surgical education, and that it may furnish an opportunity for the publication of original articles pertaining to research and investigation in those subjects which lay the foundation for sound surgical progress.[2]

In reviewing past editions of the ARCHIVES, this philosophy has been maintained over the years with remarkable consistency. The initial edition contained papers by Cushing, MacCallum, Bevan, Judd, Lewis, and Cutler—stellar surgeons of that era. Editors must stand in admiration and utter disbelief that Dean Lewis, the initial Editor, reviewed personally every paper considered for publication, a policy rapidly abandoned at his death. Thereafter, all editorial board members shared equally in the review process. Despite the early trend of publishing papers principally involving experimental surgical problems (intellectual elitism?), the policy of the editorial board gradually changed to encompass outstanding contributions and advancements in clinical surgery. The initial budget of the ARCHIVES was no less noteworthy: The Board of Trustees yearly set aside the sum of $600, which was given to the Editor to meet expenses. Gratefully these budgetary processes have undergone reasonable changes.

In the coming years the *Archives of Surgery* will adhere to the basic principle as outlined by William Mayo in the inaugural issue, ie, to offer surgeons a comprehensive journal constantly on the cutting edge of clinical surgery and relevant research. The ARCHIVES will be alert to and sensitive of duplicate publications, the challenge of controlled circulation journals, the increasing demands for supplements and festschrifts, as well as spiraling publication costs. We will encourage and seek original work and improve the time sequence of review and publication. Editorials from a wide range of individuals in the surgical disciplines will be published as the ARCHIVES offers a creative, analytical forum as we enter the 21st century.

P24,991

The Prognostic Significance of Lymph Node Metastases After Preoperative Chemotherapy for Locally Advanced Breast Cancer

David R. McCready, MD; Gabriel N. Hortobagyi, MD; Shu W. Kau, RN; Terry L. Smith, MS; Aman U. Buzdar, MD; Charles M. Balch, MD

• We compared the prognostic value of surgical lymph node staging after preoperative chemotherapy relative to other patient and tumor variables in 136 patients with locally advanced breast cancer (T3-4 and/or N2-3) who received preoperative chemotherapy followed by mastectomy and axillary dissection as part of a prospective protocol. Univariate analysis revealed that the number of metastatic lymph nodes, clinical tumor stage at presentation, clinical and pathologic response, and menopause status were significant variables associated with survival and disease-free survival, but clinical node stage at presentation and estrogen receptor status were not. The number of metastatic lymph nodes had more prognostic value than the other factors, and when evaluated by multivariate regression, surgical node staging added significantly more information to the remaining variables. Surgical staging is an important component of treatment for patients with breast cancer undergoing preoperative chemotherapy because it can provide an accurate and quantitative method for subgrouping patients with different survival rates and it can be used to compare results between preoperative chemotherapy trials.

(*Arch Surg* 1989;124:21-25)

The most important prognostic variable for patients with surgically treated breast cancer is the presence and quantity of regional lymph node metastases.[1] Surgical staging of the axillary lymph nodes has traditionally been performed before chemotherapy is offered, but many centers have started to use chemotherapy as initial treatment for patients with clinically staged locally advanced breast cancer (LABC; defined as stage III[2]).[3,4] The effect of chemotherapy, given before surgical-pathologic staging, on the prognostic significance of the number of lymph node metastases is unknown.

The purpose of this study was to determine the prognostic importance of the number of axillary lymph node metastases relative to other patient and tumor variables in patients with LABC receiving preoperative chemotherapy. Univariate and multivariate analyses were used to determine which factors were associated with survival and disease-free survival (DFS) in this group of heterogeneous patients, since favorable prognoses have been previously associated with less advanced clinical subgroups (eg, T3, N0)[5,6] and the pathologic response to chemotherapy.[7] The results of this study will allow different regimens to be compared more reliably since patient selection factors vary greatly[8] and because of the inherent inaccuracy of comparisons based on clinical axillary node stage.[9]

PATIENTS AND METHODS

In 1974, chemotherapy was begun as initial treatment at M. D. Anderson Hospital, Houston, for patients with LABC. Patients who were clinically staged to have either T3-4 and/or N2-3 breast cancer (stage III) by the American Joint Committee on Cancer criteria[2] were judged to have LABC. Patients with inflammatory breast cancer, with detectable distant metastases, or who had received prior chemotherapy, were excluded. All patients provided written consent and had a core or incisional biopsy performed to establish histologic diagnosis and, if possible, to measure estrogen receptor content. Patients were initially evaluated in joint planning clinics where medical and surgical oncologists and radiotherapists were present. This protocol, which ended in 1985, accrued 191 patients, but 17 were excluded because of major protocol violations. Thirty-one patients did not have surgery, including three patients with progressive disease and 28 in whom radiation therapy was the only locoregional treatment. Of the patients who came to surgery, a further seven did not have an axillary dissection. The remaining 136 patients who completed this preoperative chemotherapy regimen and underwent a total mastectomy with axillary dissection were followed up prospectively and formed the basis of this analysis. All the patients in this analysis were rendered disease free at the time of surgery.

Accepted for publication July 8, 1988

*Values are percentages.

The preoperative chemotherapy has been described previously[8] and consisted of fluorouracil, 500 mg/m² intravenously on days 1 and 8, doxorubicin, 50 mg/m² on day 1, and cyclophosphamide, 500 mg/m² intravenously on day 1. After three to six 21-day cycles of chemotherapy, a total mastectomy and level I and II axillary dissection was performed. Postoperatively, the patients resumed chemotherapy for six to 18 months, and then consolidative external beam radiotherapy was scheduled; some patients received their radiation therapy immediately after surgery. Following completion of all treatment, the patients were followed up at four-month intervals for the first two years, every six months for the next two years, and yearly thereafter.

Response to chemotherapy was evaluated by physical examination. A complete response was defined as total disappearance of the primary tumor and nodal disease. A partial response consisted of a greater than 50% reduction of the product of the two largest tumor diameters measured clinically. Pathologic response was graded as negative if no tumor could be found in the mastectomy specimen; microscopic residual if no tumor could be felt or seen with the naked eye but there were some viable tumor cells seen on microscopy; and gross residual if gross tumor was present. The negative and microscopic categories were combined for survival analysis because the number in each group was small. The number of axillary lymph nodes containing histologically proved breast cancer metastases was recorded by the pathologist from the mastectomy and axillary dissection specimen.

The Kaplan-Meier[10] method was used to calculate and plot the DFS and overall survival curves and the generalized Wilcoxon test was used to test differences between them.[11] Survival and DFS were calculated from the onset of chemotherapy and date of mastectomy, respectively. Patients who died without evidence of disease were counted as dead of disease in the survival analysis but were censored from DFS analysis. Survival distributions are summarized by five-year estimates to facilitate comparisons with other studies. The Cox regression model[12] was used to determine the prognostic importance of surgical node information relative to other factors. Because interest centered on whether it was important prognostically to acquire information on node status at surgery, in addition to prognostic information otherwise available, surgical node status was initially omitted from consideration and other factors were selected for inclusion in the model, using a forward selection procedure and cutoff significance level of .05. Addition of surgical node status to the selected model allowed a test of whether this information provided significant prognostic information to the already obtained factors. Associations between factors were tested by χ^2 analysis.

RESULTS

Clinical tumor stage at presentation and the clinical and pathologic response to preoperative chemotherapy and menopausal status were all important prognostic variables of survival and DFS when examined independently, but the number of metastatic axillary lymph nodes found at the time of surgery had significantly more prognostic value than the other characteristics individually and added significant information ($P<.01$) to a model using a combination of the other variables.

The pretreatment clinical staging of the patients with LABC in this study is given in Table 1. The median age was 50 years (range, 24 to 78 years), and median follow-up of the 63 survivors was 56 months (range, seven to 145 months). The overall actuarial survival and DFS at five years were 53% and 41%, respectively.

Fig 1.—Actuarial survival of patients with locally advanced breast cancer grouped according to number of metastatic axillary lymph nodes present after preoperative chemotherapy. Number of metastatic nodes was found to be significant prognostic variable of survival by univariate analysis (Wilcoxon, $P<.001$) and multivariate analysis (Cox, $P<.01$).

Univariate Analysis

Differences in survival and DFS according to the number of positive nodes were highly statistically significant, with a marked linear trend for decreased survival associated with increasing number of nodes. Survival and DFS of patients grouped by the number of positive nodes (0, 1 to 3, 4 to 10, and >10) are illustrated in Figs 1 and 2. The survival (±SE) at five years of patients with no positive axillary lymph nodes was 70%±9%, and was 62%±8% if one to three metastatic nodes were present, 47%±9% for patients with four to ten positive nodes, and 21%±8% if greater then ten nodes with metastases were found ($P<.001$). The five-year DFS was 72%±8%, 46%±8%, 35%±9%, and 6%±6%, respectively, and these differences were significant ($P<.001$). If patients with greater than or equal to four nodes were considered as one group, survival at five years was 38% and the DFS was 20%.

Two important subgroups were identified using the surgically staged node information. Patients with negative axillary nodes had an excellent prognosis, with a median survival of 91 months, but the 24 patients with more than ten positive nodes had a dismal survival rate. Only three patients in the subset are currently alive, and two of these have bone metastases. Six patients had disease recurrence within eight months of surgery.

Patients who presented with clinical stage T4 breast cancer, that is, the tumors extended into the chest wall or

produced edema (including peau d'orange) or ulceration of the skin overlying the tumor, had worse prognoses (five-year survival, 42%; DFS, 30%) than those patients with less extensive primary tumors (T1-3; five-year survival, 78%, $P=.002$; DFS, 64%, $P<.001$). Clinical tumor stage at presentation was second only to the number of metastatic nodes in prognostic value when examined independently (Table 2).

Complete clinical response to the preoperative chemotherapy was associated with a significantly increased survival (94% at five years, $P=.01$) and DFS (87%, $P=.01$), but there was little difference between those patients who had a partial response and those who had no response (Table 2). Pathologic assessment of the mastectomy specimen revealed that patients with no discernible residual tumor or microscopic residual tumor (65% five-year survival, 70% DFS) after preoperative chemotherapy had significantly better survival and DFS than those patients with gross residual breast cancer remaining after preoperative chemotherapy (five-year survival, 49%, $P=.03$; DFS, 33%, $P=.001$).

Patients who were premenopausal had significantly better survival ($P=.04$) and DFS ($P=.002$) than did postmenopausal patients (Table 2), but clinical node stage at presentation was not a significant predictor of survival ($P=.08$) or DFS ($P=.06$). There were few differences in survival or DFS of the patients with tumors high in estrogen receptors compared with those with low estrogen receptor content.

Multivariate Analysis

To determine whether the number of metastatic lymph nodes added more prognostic information to other patient or tumor variables, the factors listed in Table 2 were evaluated for stepwise inclusion in Cox regression models of survival and DFS. The number of positive nodes was initially excluded from consideration. Factors selected for inclusion were clinical tumor stage at presentation, clinical response, and menopause status (Table 3). Models were then fit that included these terms plus a fourth term indicating the number of positive nodes after preoperative chemotherapy. The improvement in the fit of the model was statistically significant ($P<.01$) and suggests that surgical lymph node staging can significantly increase the prognostic information otherwise available.

Associated Factors

The number of involved lymph nodes was significantly associated with both clinical ($P<.01$) and pathologic ($P=.02$) response to chemotherapy, but pretreatment clinical tumor stage, clinical node stage at presentation, or menopausal status were not associated with the number of positive nodes (Table 4). The absence of nodal metastases tended to parallel pathologically determined chemotherapeutic response in the primary cancer. Sixteen (52%) of 31 patients who had no gross residual breast cancer had no positive lymph nodes, and none of these patients with minimal amounts of residual cancer had more than ten metastatic nodes. Similarly, ten (59%) of 17 patients who experienced a complete clinical response had no positive lymph nodes at surgery.

COMMENT

The objective of this study was to determine whether preoperative chemotherapy altered or diminished the value of surgical lymph node staging in patients with LABC. These results demonstrate that the presence and quantity

Fig 2.—Actuarial disease-free survival of patients with locally advanced breast cancer grouped according to number of axillary lymph nodes with metastases after preoperative chemotherapy. Number of positive nodes was most significant prognostic variable for disease-free survival by univariate (Wilcoxon, $P<.001$) and multivariate regression analysis (proportional hazards, Cox, $P<.01$).

of lymph node metastases remains the most important prognostic variable associated with survival and DFS after preoperative chemotherapy for patients with LABC. Menopausal status, clinical tumor stage at presentation, and response to chemotherapy are also individually important.

Patients with LABC are heterogeneous with respect to prognosis.[6] This heterogeneity, combined with the lack of a consistent definition of LABC and the inherent inaccuracy related to clinical staging, make comparisons between treatment regimens difficult. The survival differences reported between treatment modalities may be more the result of patient selection than the effects of therapy.[8] Surgical-pathologic staging should result in more reliable treatment comparisons.

Traditionally, staging and, by definition, the measurement of prognostic variables are performed at the time of definitive surgical treatment. It is not surprising that some variables can lose their predictive value when other therapeutic modalities are initiated before surgery. Preoperative radiotherapy has been shown to obviate the prognostic value of Haagenson's grave signs, size of the primary tumor, and clinical node status.[13] Clinical node stage at presentation and estrogen receptor status were not significant after preoperative chemotherapy in this series.

There were 34 patients (25%) who had no metastatic axillary nodes after preoperative chemotherapy, which is double the number of patients with negative nodes found in stage III breast cancer treated with radical mastectomy without preoperative intervention.[14] This increased nega-

*By generalized Wilcoxon test.[11] DFS indicates disease-free survival.
†The receptor status was unknown in 31 patients.

Table 3.—Multivariate Analysis*

Independent Factors	Survival: Order of Entry	Survival: P	DFS: Order of Entry	DFS: P
Surgical node staging†	. . .	<.01	. . .	<.01
Clinical tumor stage at presentation	1	<.01	1	<.01
Clinical response	2	.01	3	.02
Menopausal status	3	.04	2	.01

*DFS indicates disease-free survival. Analysis by proportional hazards model of Cox.[12] Regression equation for survival: $1n[\lambda(t)/\lambda o(t)] = +0.380(N) - 0.950(T) - 1.790(Response) - 0.396(Menopause)$; regression equation for DFS: $1n[\lambda(t)/\lambda o(t)] = +0.568(N) - 1.003(T) - 0.518(Menopause) - 1.243(Response)$. For these equations, codes for covariates are as follows: surgical nodes (N), no nodes, 0; one to three nodes, 1; four to ten nodes, 2; over ten nodes, 3; menopausal status, postmenopausal, 0; premenopausal, 1; tumor grade (T), T1-3, 1; T4, 0; response, partial or no response, 0; complete response, 1.

†The number of metastatic nodes had the highest score statistic, and the addition of this surgical staging variate resulted in significantly more prognostic information than a combination of the strongest other factors (see "Patients and Methods" section).

Table 4.—Associated Factors

Characteristic	No. of Nodes With Metastases: 0	1-3	4-10	>10	P

tive node rate suggests lymph node metastases may be influenced by preoperative chemotherapy in those patients with responsive tumors. Variables that reflect response (number of lymph node metastases, clinical response, and pathologic response) and are thus measured after initial treatment may be more valuable than those measured at presentation.

The accuracy of surgical staging after preoperative chemotherapy may be the result of three factors. The number of positive lymph nodes is a quantifiable characteristic, is an index of systemic disease,[15] and is influenced by the cancer's response to chemotherapy, thus reflecting any downstaging that has occurred.

The absence of nodal metastases was significantly associated with a complete clinical and pathologic response in this series, and this suggests that downstaging of the nodal metastases paralleled the reduction of the primary cancer. The improved survival of subgroups of these downstaged patients (ie, those with complete clinical or pathologic response) also implies that prognosis depends on the amount of tumor present after chemotherapy rather than the tumor stage at presentation.

Further evidence of downstaging is provided by comparing the DFS from adjuvant postoperative chemotherapy trials for clinical stage I and II (pathologic stage T1-2, N1) breast cancer with that of our series for LABC after preoperative chemotherapy. The Milan group[16] has reported five-year survival rates for patients with one to three, four to ten, and greater than ten positive nodes of approximately 60%, 45%, and 38%, respectively, and in our series the respective survival was 62%, 47%, and 21%. However, it must be mentioned that other series have reported higher survival rates with adjuvant chemotherapy.[17]

Surgery is an integral component of the multimodality management of patients with LABC because mastectomy can improve local control,[18,19] and surgical staging provides important prognostic information. The subgroup of patients with greater than ten metastatic nodes after preoperative chemotherapy had a very poor prognosis. A more aggressive postoperative chemotherapeutic regimen is being planned for these patients with the hope that other agents will be able to prolong survival. Future protocols designed to employ only chemotherapy and radiotherapy without surgical staging will be unable to stratify and identify these subgroups of patients that may benefit from different treatments.

We wish to acknowledge the expert help of Mamie Gatlin and Janice Webb in typing the manuscript.

Discussion

Q Would you please clarify your definition of response?

A We used two different responses: clinical response and pathologic response. The 17 patients alluded to first were clinical responders. They had complete clinical response; there was no tumor felt. Some of those had microscopic tumor in the mastectomy specimen, and some of them even could have had gross tumor that might be found once the breast was cut. But there were two separate measurements: clinical and pathologic.

Q But you said that of those 17 who had a complete clinical response, only one had a recurrence in five years.

A Only one died; that was a survival curve. I believe there were three recurrences.

Q In those patients who had a complete response, could you argue for not doing a full level I and II nodal dissection and just simply removing a few nodes, or not removing any, since 85% had no nodes involved?

A That could be an argument. There were no patients with more than ten nodes. While doing the mastectomy to show that there is no gross or residual tumor, I do not think it adds much to sample those lateral axillary nodes.

Q Would inadequate sampling contribute to apparent node negativity?

A The median number of nodes found was 13. In Dr Fortner's series of operable stage III breast cancer, there was a 12% incidence of negative nodes; there was about a 25% incidence in this series. I do not have the number of nodes actually sampled from his study to account for that. These were lateral axillary dissections, and I do not really know what our historical control would be for lateral axillary dissections, or how many nodes would be involved. I am not sure if the number of nodes is less after preoperative chemotherapy. It seems that the number of positive nodes is less, but I am not sure if the number of nodes found is less.

A Comparison of Palpable and Nonpalpable Breast Cancers

Timothy J. Pagana, MD; Willem J. Lubbe, MD; Sheldon M. Schwartz, MD; Gene D. Sprechini, PhD

• Chi-square statistics were used to compare prognostic factors of 60 patients with nonpalpable breast cancer (NPBC) and 112 patients with palpable breast cancer. Noninvasive cancers were more frequent, tumor size was smaller, and nodal metastasis was significantly less frequent in the NPBC group. However, the frequency of nodal metastasis was similar when adjusted for size and grade. There was no significant difference in the incidence of age and menopausal status of the patients, histologic types, hormone receptor status, and histologic/nuclear grade between these two groups. The findings were consistent with the hypothesis that NPBCs are potentially lethal tumors and that mammograms detect them earlier, ie, these tumors are smaller, localized, and, therefore, more curable.

(*Arch Surg* 1989;124:26-28)

The mortality for breast cancer has not changed in the last 30 to 40 years. All recent improvements in surgery, chemotherapy, and radiation therapy have not improved survival.[1,2] Unfortunately, the present knowledge of the risk factors of breast cancer does not provide a basis for reducing its incidence. In an effort to reduce the mortality, many large studies have evaluated the benefit of early detection on survival of patients with breast cancer. Recent reports[3,4] have indicated an improved survival among certain populations of mammographically screened patients. This has led to a dramatic increase in the number of women undergoing screening mammography. As a result, more nonpalpable breast cancers (NPBCs) are being detected. But, are these "tiny" nonpalpable mammographically detected cancers "real" cancers? There has been some contention that many of these small cancers are not life threatening, would not be expected to progress to the point of metastasis, and would remain unchanged indefinitely if left untreated.

In an attempt to determine whether or not NPBCs are "killer" cancers, we compared prognostic factors of NPBCs and palpable breast cancers (PBCs) detected at our institutions.

PATIENTS AND METHODS

The sample consisted of 172 women whose conditions were diagnosed as breast cancer from a group of 482 patients who had undergone breast biopsies. Information was collected on the 60 women (35%) with NPBC and the 112 women (65%) with PBC. All women were consecutively treated at our institutions (Divine Providence Cancer Treatment Center, Williamsport, Pa, or The Williamsport [Pa] Hospital and Medical Center) between 1983 and 1987. These two groups of women with breast cancer were compared with respect to age, menopausal status, histologic type, histologic grade, hormone receptor status, size, and incidence of lymph node metastasis. Invasive cancers were given histologic grades according to the system described by Fisher et al.[5,6] Noninvasive cancers were given a nuclear grade by using criteria also described by Fisher and colleagues[5,6] in the same reports. Chi-square tests were used to make most comparisons that involved incidence; *t* tests were used to compare means.

RESULTS

Histology

Of the 60 NPBCs, 42 (70%) were invasive ductal, two (3%) were invasive lobular, 15 (25%) were intraductal, and one (2%) was noninvasive lobular. Of the 112 PBCs, 101 (90%) were invasive ductal, seven (6%) were invasive lobular, three (3%) were intraductal, and one (1%) was noninvasive lobular. A χ^2 test indicated that there was a significantly greater percentage of noninvasive cancer in the NPBC group ($P = .0001$). When noninvasive cancers were excluded, a χ^2 test showed no significant difference in histology between the two groups ($P = .73$).

Size

A *t* test showed that the cancers in the NPBC group were significantly smaller ($P = .0001$) than the PBC group (Table 1). The median and mean size of the NPBC group were 1.0 and 1.3 cm, respectively. The median and mean size for the PBC group were 2.0 and 2.4 cm, respectively.

Age and Menopausal Status

A *t* test yielded no significant difference between the mean age of the NPBC group (61 years) and the mean age of the PBC group (63 years) ($P = .17$). Likewise, no significant difference was found in menopausal status among the two groups (χ^2 test, $P = .33$). Fifteen patients (25%) of the

Positive	Positive	17	40
Positive	Negative	12	11
Positive	ND	3	7
Negative	Positive	1	4
Negative	Negative	15	35
Negative	ND	2	3
Total Positive		**33**	**62**
Total Negative		**17**	**38**
ND		10	12

*NPBCs indicates nonpalpable breast cancers; PBCs, palpable breast cancers; ER, estrogen receptor; PR, progesterone receptor; and ND, not done. Significance by χ^2 test, $P = .64$.

NPBC group and 21 patients (19%) of the PBC group were premenopausal.

Histological/Nuclear Grade

Chi-square tests were used to compare histologic and nuclear grades. Histologic grades of invasive cancers were similar among the two groups ($P = .91$). Among the NPBC group, three (7%) were grade 1, 19 (43%) were grade 2, and 22 (50%) were grade 3. Among the PBC group, seven (6%) were grade 1, 43 (40%) were grade 2, and 58 (54%) were grade 3. The nuclear grade of noninvasive breast cancers was also similar ($P = .08$), although the percentage of noninvasive cancers was small in the PBC group. Among the NPBC group, four (25%) were grade 1, eight (50%) were grade 2, and four (25%) were grade 3. Among the PBC group, two (50%) were grade 1, two (50%) were grade 2, and none were grade 3.

Hormone Receptor Status

No significant difference in the hormone receptor status between the two groups was found with a χ^2 test. Thirty-three patients (66%) of the NPBC group were hormone receptor positive, and 62 patients (56%) of the PBC group were positive ($P = .64$). In ten of the nonpalpable cancers and 12 of the palpable cancers, no hormone receptive assay was obtained (Table 2).

Lymph Node Status

The results of a χ^2 test indicated that the NPBC group, as a whole, had a significantly lower incidence of nodal metastasis than their palpable counterparts ($P = .0001$). Six patients (10%) of the NPBC group and 46 patients (45%) of the PBC group had positive lymph nodes. This difference was still significant even when noninvasive cancers were excluded from both groups. However, the significant difference disappeared when similar size and grade tumors were compared (Table 3).

COMMENT

Breast cancer occurs in one out of ten American women.[7] Detection after metastasis has occurred leads to immeasurable personal suffering and financial cost. Detection and treatment of breast cancer before metastasis has occurred should be associated with decreased morbidity and mortality. We have shown, as have others,[8-11] that the use of screening mammography in asymptomatic women can detect small cancers that are rarely associated with metastasis. But, are these nonpalpable neoplasms really cancer caught at an "early" stage? Or, are they a more "benign" form of breast cancer that would never develop any further during the life of the patient? There are no reliable pathohistologic criteria that can resolve these questions. Legal and ethical standards would preclude completion of a study designed to follow untreated NPBCs for a long period of time. Also, the performance of a diagnostic biopsy usually completely removes these tiny cancers and, thereby, eliminates the opportunity to study a group of patients who may refuse treatment.

Several investigators have attempted to resolve this dilemma. Moskowitz[12,13] performed mammogram screening on over 10 000 women. If he had found an exaggerated incidence of breast cancer in this screened population, he could have concluded that the use of screening mammography detected clinically significant plus clinically insignificant breast cancers. Instead, he found that the incidence of cancer in the screened population was not significantly different from the incidence of cancers otherwise expected in this population. That is to say, he did not detect an exaggerated incidence of breast cancers in the screened population. He concluded that tiny cancers detected by screening mammography would have become clinically significant if left untreated. Brinton et al[14] arrived at the same conclusion by comparing the risk factors of small and large invasive cancer groups; they showed a close similarity between the risk factors of these two groups of breast

cancers, thereby supporting the notion that these two groups are biologically closely related.

We have chosen to compare reliable prognostic factors of NPBCs and PBCs to see if they may act similarly aggressive. The prognostic variables included patient age and menopausal status, tumor size, hormone receptor status, histology, histologic grading, and the incidence of lymph node metastasis. Not all of these factors, however, are a measurement of the intrinsic activity of breast cancer alone. Some of these factors are also a result of other aspects of the clinical situation. For example, while tumor size may be a measure of the intrinsic nature of breast cancer, it is also reflective of a duration of growth.[15] Likewise, while the incidence of lymph node metastasis may be the most important prognostic factor of breast cancer, it is also a result of many other prognostic variables, such as tumor size and histologic grade.[15,17] Therefore, by and of itself, tumor size and the incidence of lymph node metastasis cannot be studied as independent accurate indicators of the intrinsic nature of breast cancer. With regard to the incidence of lymph node metastasis, it is interesting to note that there was no statistically significant difference between the two groups when the size and histologic grade were kept constant. This serves to indicate comparable aggressiveness between these two groups. The numbers within these subgroups are small, however.

Histologic grading and hormone receptor status are, independently, most reflective of the intrinsic nature of breast cancer.[18-22] These are probably not related to other factors, such as duration of growth and size. In our study, we found no difference between the NPBC and PBC groups with regard to histologic grading or hormone receptor status, further supporting a biologic similarity between the two groups.

Although we have shown that NPBCs were smaller, were less frequently infiltrating, and were generally associated with a lower incidence of lymph node metastasis when compared with their palpable counterparts, there was no difference between these two groups of cancers with regard to age and menopausal status of the patient, size/grade–adjusted incidence of lymph node metastasis, histology, histologic/nuclear grade, and hormone receptor status. We conclude, therefore, that because of their similarity with PBC, tiny NPBCs are not just a benign form of breast cancer that may never kill. Rather, we suggest that NPBCs are potential killer cancers detected in their preclinical state. If left undetected or untreated, they could develop into a palpable cancer that would metastasize and kill.

This report, however, does not attempt to resolve whether or not noninvasive breast cancer represents an "earlier" stage of invasive cancer. Most investigators, however, believe that this is a natural progression, especially for ductal cancer. We agree, and in light of our data, therefore, encourage the use of screening mammography for asymptomatic women in high-risk categories. We believe this screening diminishes mortality because it detects cancers earlier and at a time when treatment can provide an excellent opportunity for cure.

We appreciate the consulting assistance of Kathleen D. Pagana, RN, PhD, in the preparation of this manuscript.

Discussion

Q How do you define nonpalpable, and how do you perform biopsy on NPBCs?

A Nonpalpable was described as capability of the clinician to palpate the neoplasm. All of these tumors underwent biopsy with the use of preoperative x-ray localization and all of the tumors had postoperative roentgenograms of the mammogram specimen.

Q I am still a little confused about this study. Are we to conclude that nonpalpable, noninvasive, intraductal carcinoma is potentially a killer cancer from this analysis?

A No. We do not purport to resolve the problem of noninvasive cancers becoming invasive killer cancers; that would require the study of noninvasive cancers in a longer follow-up of that group.

Q Was size a discriminating factor as to whether or not to perform biopsy?

A We do not consider size to be a discriminating factor as to whether or not we should take a biopsy specimen of a lesion. If the lesion is new or if the lesion has irregular borders or, in any way, looks suspicious or is associated with microcalcification, we will proceed with a biopsy.

Q How many of the nonpalpable cancers were, in fact, associated with microcalcifications? Was that the common presenting mammographic finding?

A Thirty percent of microcalcifications were cancerous; likewise, nearly 30% of breast nodules without calcification were cancerous, and the combination of calcification in a mass did not really increase the incidence of cancer. Therefore, around 60% of the NPBCs had microcalcification within.

Nonpalpable In Situ Ductal Carcinoma of the Breast

Predictors of Multicentricity and Microinvasion and Implications for Treatment

Gordon F. Schwartz, MD; Arthur S. Patchefsky, MD; Sidney D. Finklestein, MD; Sae H. Sohn, MD; Anthony Prestipino, MD; Stephen A. Feig, MD; Jodi S. Singer, MD

• Fifty breasts with nonpalpable ductal carcinoma in situ (DCIS) were examined for the presence of microinvasion, multicentricity, and number of involved ducts to see if the biopsy specimen could have predicted the findings in the remainder of the breast. When DCIS was an incidental finding, fewer ducts were involved and no evidence of either microinvasion or multicentricity was found. Solid and cribriform DCIS were rarely multicentric or microinvasive; micropapillary DCIS was often multicentric, rarely microinvasive; comedocarcinoma was more likely to be both microinvasive and multicentric. Ductal carcinoma in situ as an incidental finding may be treated by excision alone; papillary and micropapillary DCIS are best treated by therapy aimed at the entire breast, although axillary dissection may not be required. Therapy for comedocarcinomas should include the entire breast and the axillary nodes.

(*Arch Surg* 1989;124:29-32)

Until we solve the mystery of breast cancer prevention, how fortunate our patients would be if we could promise them the detection of this dread disease when it was nonpalpable, noninvasive, and nonthreatening. In recent years, the ubiquitous use of screening mammography in asymptomatic women has led to the earlier detection of breast cancer as clusters of microcalcifications, nonpalpable masses, and areas of parenchymal distortion, without any overt clinical evidence of disease. Many of these malignant neoplasms are not yet invasive, and the frequent diagnosis of ductal carcinoma in situ (noninvasive) (DCIS) has become a consequence of these screening mammograms. Although described rarely before this era, one third of patients in our own series of over 300 breast cancers detected by mammography had DCIS or DCIS with microinvasion.[1] Small is not a synonym for inconsequential, since 30% of clinically nonpalpable, frankly invasive cancers may have axillary metastasis, but none of this published group of patients with DCIS had a positive axillary node.

If specific identifiable characteristics of DCIS that determine the likelihood of associated multicentricity or microinvasion exist, they might be used to predict what might be occurring in the remainder of the breast or in the regional nodes. Thus, the biopsy findings might then determine what, if any, further treatment might be required in each individual patient with DCIS. If node metastasis is unlikely, then axillary dissection could be avoided in selected patients; there might be a group of patients with DCIS confirmed on biopsy for whom no further treatment might be reasonable.

This study was designed to attempt to answer these questions by comparing biopsy and subsequent mastectomy findings in women with DCIS. Mastectomy specimens in patients with nonpalpable DCIS were examined for residual tumor at the biopsy site, accompanying microinvasion, multicentricity, and axillary node metastasis, so that we could determine if the biopsy findings could predict the status of the entire breast and axilla. A strong positive correlation between biopsy findings and breast status would have significant implications for treatment, permitting therapeutic decisions on the basis of the biopsy results alone.

PATIENTS AND METHODS

Records of the pathology department and tumor registry of Thomas Jefferson University Hospital, Philadelphia, were reviewed for the years between 1970 and 1985 for patients indexed as having DCIS or DCIS with microinvasion. Patients with palpable masses that proved to be malignant, even if the biopsy demonstrated only DCIS, were excluded. If, however, a palpable mass led to biopsy, but the mass itself was benign and DCIS was an incidental finding in the biopsy specimen, the patient was

Reprint requests to 1015 Chestnut St, Suite 510, Philadelphia, PA 19107 (Dr Schwartz).

included. Women with Paget's disease, if there was no evidence of invasive cancer and no accompanying breast mass, were also included, as were patients with nipple discharge without an accompanying mass. Patients with lobular carcinoma in situ (lobular neoplasia) were excluded.

Mastectomy was an important criterion for inclusion in this study so that the entire breast would be available for microscopic examination. Thus, the study group included patients who underwent total mastectomy alone, mastectomy with axillary dissection (modified radical mastectomy), or radical mastectomy. Parenthetically, the diagnosis of DCIS has been made more frequently in recent years than before 1980. Many of our recent patients have chosen breast conservation, usually wide local excision, axillary dissection, and irradiation, and, therefore, could not be included in this study.

Biopsy and mastectomy specimens were processed in the surgical pathology department according to a standard protocol. The following details about each specimen were recorded: (1) Histologic pattern of DCIS. The patterns of papillary, micropapillary, solid, cribriform, or comedocarcinoma were used. When more than one type was present, the specimen was assigned to the diagnosis that predominated. (2) Presence of microinvasion at the biopsy site. We have previously defined microinvasion as mainly a DCIS showing focal microinvasion below the basement membrane in one or several individual ducts, but in not more than 10% of the surface of the histologic sections examined.[2] (3) Number of involved ducts, ie, the cross-sectional duct structures containing tumor in all of the tumor-bearing slides. All of the biopsy material was submitted for study; the average number of slides per biopsy specimen was eight. Total number of ducts involved was recorded by adding the numbers of ducts involved in each slide, including both the biopsy material and the site of the biopsy in the subsequent mastectomy specimen. Counting the total number of involved ducts in both specimens, biopsy and mastectomy, minimized any variations in number of involved ducts due to differences in biopsy size. Cancerization of lobules was counted as a single ductal unit. (4) Presence of multicentric ductal carcinoma in the mastectomy specimen.

Mastectomy specimens were processed according to the protocol outlined by the Pathology Working Group of the National Breast Cancer Task Force.[3] A minimum of four sections was provided from each quadrant as well as four sections from the retroareolar area. Multicentricity was defined as the presence of invasive ductal or lobular carcinoma, microinvasive ductal carcinoma, or DCIS in an area or quadrant outside the biopsy site. The presence of lobular carcinoma in situ at the biopsy site or elsewhere was ignored in the determination of multicentricity. If the lesion was centrally located, deep to the nipple-areolar complex, the cancer was considered multicentric only if additional foci of carcinoma were found outside a perimeter of 5 cm from the edge of the nipple and areola. Axillary nodes, when included, were divided into three anatomic groups using levels defined by the pectoralis minor muscle. Nodes were found by hand dissection of the fresh specimens, and each node was cut at one level unless it was large enough to warrant more sections.

RESULTS

The study group comprised 47 women, 29 to 75 years of age (mean, 56 years; median, 57 years), with 50 DCISs, three women having synchronous bilateral cancers (Table 1). Patients were followed up through June 30, 1987, with a mean follow-up of 7.7 years and a median follow-up of seven years. Mode of presentation is shown in Table 2. Thirty-two breasts altogether (64%) had undergone biopsy for suspicious mammographic findings, and in 29, DCIS was the lesion responsible for the mammographic finding. Fourteen of these lesions were comedocarcinomas. In three women with mammographic abnormalities, the DCIS was an incidental finding, with the lesion provoking the biopsy being benign. Each patient with bilateral in situ carcinoma had the same mode of presentation in each breast.

The mode of detection apparently influenced the likelihood of both multicentricity and microinvasion, as noted in Tables 3 and 4. Of the 50 breasts studied, 18 (36%) contained multicentric foci of DCIS, one patient having both multicentric DCIS and invasive ductal cancer in the same breast as well as a single positive level I axillary node. No other patient had multicentric foci of more aggressive carcinoma than that found in the biopsy specimen. The DCIS presenting as nipple discharge or as Paget's disease was accompanied by a greater incidence of multicentricity than was DCIS detected by mammography or as an incidental finding. Thirteen breasts with DCIS (26%) demonstrated microinvasion in the biopsy specimen. The cancers detected mammographically were more likely to be microinvasive than those presenting with nipple discharge or erosion. None of the patients in whom DCIS was detected incidentally had either multicentric or microinvasive cancer.

*DCIS indicates ductal carcinoma in situ.

With respect to the numbers of involved ducts in patients with DCIS, 20 (40%) of the 50 breasts examined had ten or fewer ducts involved, but ten breasts (20%) had 100 or more involved ducts. As might be expected, patients in whom DCIS was an incidental finding had the smallest number of involved ducts (mean, seven ducts), and these were mostly papillary, cribriform, and solid histologic types of DCIS. The number of ducts involved by DCIS correlated with multicentricity more than it did with microinvasion, but multicentric and microinvasive carcinomas were scattered throughout all levels of ductal involvement, even among those cases with minimal numbers of involved ducts. There was no "safe" level of duct involvement below which neither multicentricity nor microinvasion was evident. However, in every patient but one (who presented with nipple discharge), if more than 100 ducts were involved by DCIS, multicentricity was also noted. There was no significant number of involved ducts—a "breakpoint"—that implied microinvasion; the 13 breasts with microinvasive DCIS had levels of duct involvement ranging from ten to 571. Although a trend toward microinvasion was noted as the number of involved ducts increased, several patients with the greatest numbers of involved ducts did not have accompanying microinvasion.

The incidence of multicentricity and microinvasion in each histologic type of DCIS is noted in Tables 5 and 6. Although few in number, solid and cribriform DCIS were never multicentric and rarely microinvasive; papillary DCIS was rarely either multicentric or microinvasive. Micropapillary DCIS was frequently (six of seven) multicentric but rarely microinvasive. Comedocarcinomas were more likely to be either multicentric or microinvasive than the other histologic varieties of DCIS; two such lesions, with seven and 11 involved ducts, respectively, demonstrated microinvasion and multicentricity. The only patient with multicentric invasive carcinoma and an involved axillary node had a comedocarcinoma detected as mammographic calcifications, with 224 involved ducts and microinvasion detected in the biopsy specimen.

COMMENT

The diagnosis of DCIS has become more common as the use of mammography for screening asymptomatic women has become an accepted component of optimal health care. However, a variety of macroscopic and microscopic lesions are classified by this same term or synonyms, eg, DCIS, intraductal carcinoma, noninvasive duct carcinoma, and, until recently, palpable and mammographically detected tumors have not been categorized separately with respect to treatment or outcome.

None of the 50 cases of DCIS reported in this study presented as a palpable malignant mass in the breast. Eleven cases had clinical evidence of disease, ie, seven with nipple discharge and four with nipple erosion. Twenty-nine breasts underwent biopsies because of microcalcifications that proved to be malignant, and the remaining ten cases of DCIS were truly incidental findings in patients undergoing biopsy for either palpable or mammographic findings that proved benign.

Recognizing that the number of breasts examined was small, our observations concerning the number of involved ducts, microscopic tumor type, multicentricity, and microinvasion have several implications. Comedo and micropapillary forms of DCIS were more likely to be multicentric than were papillary, cribriform, and solid types, and comedocarcinomas alone were likely to be accompanied by microinvasion. In comedocarcinoma, even the small ones (involving few ducts) demonstrated this proclivity to microinvasion, implying a relatively short noninvasive growth phase. The micropapillary form of DCIS, strongly correlating with multicentricity but not with microinvasion, perhaps arises in multiple foci simultaneously but remains indolent for a longer time.

The most interesting group of patients was the group in which DCIS was an incidental finding. None of these patients had either multicentric DCIS or evidence of microinvasion. These lesions also tended to be small, all but one involving 20 ducts or less, none involving more than 35 ducts. There was only one comedocarcinoma in this group that involved only five ducts. All of the incidental in situ carcinomas discovered by mammography were adjacent to the benign lesion. The three incidental in situ carcinomas found in palpable breast disease were more difficult to localize with respect to the dominant benign lesion since these specimens were larger. Perhaps the lack of multicentricity or microinvasion in these incidental in situ carcinomas denotes a subset of DCIS with a less aggressive biologic potential.

This study also establishes that there is no safe (minimum) level of duct involvement that guarantees against multicentricity or microinvasion. As already noted, however, DCIS of the solid or cribriform types and those that are accidental discoveries are seemingly less aggressive than those that are comedocarcinomas.

The studies of DCIS that address the question of the natural history of untreated disease imply that 30% to 50% of these patients will subsequently develop an invasive carcinoma of that breast.[4,5] Current treatment recommendations are at least in part a reflection of the uncertainty of this prediction. If there were a means by which these odds could be defined more reliably in each particular situation, therapy could be tailored more precisely and individually. This concept has been recognized and already implemented to some degree by Gump et al,[6] Silverstein et al,[7] and Schnitt et al,[8] but without clear-cut guidelines for treatment based on an accurate assessment of risk of multicentricity, microinvasion, or axillary node metastasis.

If our observations in this small number of patients are confirmed so that the qualitative and quantitative characteristics of DCIS within the entire breast may be approximated by the detailed evaluation of the biopsy specimen, patients may be informed of their treatment options with greater certainty that the most suitable strategy will be suggested. If any patients, for example, are chosen for treatment by excision alone, without further attention to the remainder of the breast or to the regional nodes, it should be those women in whom the diagnosis of DCIS is an incidental finding. Women with nonpalpable solid or cribriform types of DCIS are also candidates for excision only, if the biopsy indicates a small number of involved ducts. Women with nonpalpable papillary or micropapillary subsets of DCIS apparently are still best served by treatment of the entire breast, either by mastectomy or irradiation, but axillary dissection is probably not indicated. Women with comedocarcinoma are at higher risk for microinvasion than those with other forms of DCIS. Although the risk of axillary node metastasis is small (one patient in this series), at least level I axillary dissection should be considered for those women with comedocarcinomas with large numbers of involved ducts or with documented microinvasion in the biopsy specimen.

Although not specifically addressed by this study, we concur with Gump et al[6] that macroscopic (palpable) DCIS should not be considered in the same way as nonpalpable DCIS. Patients with macroscopic disease deserve the same treatment as those with invasive carcinomas of the same size, with the recognition that axillary metastasis is less likely and the outcome more favorable.

Until the recent popularity and widespread acceptance of breast-conserving procedures, the threat of mutilation often impeded the early detection of breast cancer, since the reward for diligence was perceived as more threatening than the disease itself. As we continue to refine therapy to fit individual patient circumstances, it is a reasonable expectation that still earlier discovery will continue to be paralleled by lesser and lesser treatment.

Discussion

Q May I ask you about how you quantitate the number of ducts? Since the duct is a branching structure, it seems that the frequency of your sections would determine the number of involved ducts.

A We counted the number of ducts on serial sections. This was determined by having two separate pathologists count the tubular structures that they could see to arrive at a consensus. The comments you make, in terms of serial sections, are well taken, and an attempt was made to try to avoid that in counting the ducts. To some degree this was subjective.

Q In reference to the mammographic findings, I presume the incidental finding was one in which the mammogram did not detect the lesions at that site. Please clarify this.

A Several of the patients had palpable masses and, of course, the DCIS was an incidental finding elsewhere in the specimen, not in the palpable mass. In the patients who had DCIS as an incidental finding, several had calcifications as the finding on the mammogram, but the calcifications were totally benign, such as microscopic cystic disease or another diagnosis, and the DCIS was not associated with the area of calcification.

Q Is there a relationship then in your overall study between the mammographic findings and multicentric involvement in either areas of calcifications or otherwise?

A Only in one sense. I think it is more important to determine not so much what the mammographic findings might be, but how the mammographic findings are correlated with the histologic features; those mammographic findings that proved to be calcifications within the ducts of a carcinoma were much more likely to be associated with both multicentric and microinvasive carcinoma. We can see calcifications that are extraductal in patients who have cribriform, papillary or micropapillary types of carcinoma, but when the calcifications were seen as little purple spots right in the middle of the carcinoma, this type was more likely to be associated with multicentricity and microinvasion.

Q Did I understand that one patient in your series had positive axillary nodes and that an invasive breast cancer was incidentally found at a site remote from the intraductal site?

A That's correct.

Q Then why are you advocating node dissections?

A Well, it depends whether one looks at this as mostly negative or possibly positive. The latter approach is safer. I certainly only advocated node dissections in those patients with carcinomas who had high ductal involvement and who had microinvasion at the site. Those were the only patients for whom I had advocated lymph node dissection.

Breast Carcinoma In Situ

• A total of 150 patients with in situ breast cancer were treated from 1970 through 1976, with a median follow-up of 11.5 years. There were 42 patients with microinvasion and 25 with bilateral disease, analyzed separately. Eight patients who became unavailable for follow-up within five years (but who had no evidence of disease [NED]) were excluded. Eighty-five patients had ductal carcinoma in situ, 43 had lobular carcinoma in situ, and 22 had a mixed type. Modified radical mastectomy was done in 112 cases. One of 128 patients had positive axillary nodes; axillary dissection is not indicated for in situ breast cancer. Of the 150 patients, one with ductal disease died of disease. Six died of other causes, free of disease. Of 18 treated by excision alone, two underwent mastectomy for recurrence and had NED. Patients with microinvasion had involved nodes in 10%, and 94% had NED. However, all bilateral cases had NED.

(*Arch Surg* 1989;124:33-36)

Retrospective analyses of patients with in situ breast carcinoma showed that most patients were treated by mastectomy, and that survival rates, free of disease, were over 90% and approximated 100%.[1-3] Often these series did not have long-term follow-up[4-6] and/or did not include pathologic analysis of failures.[7] The latter included higher-than-expected incidences of axillary node involvement or a higher rate of distant metastases than would have been expected.[8]

Some of these problems were due to definition; before the use of mammography, patients with ductal carcinoma in situ (DCIS) presented with clinical findings. They had either a mass, Paget's disease of the nipple, or bloody nipple discharge. Haagensen[9] considered that all such patients had microinvasion and should be treated by radical mastectomy. This definition allowed up to 50% of such lesions to be invasive. It was not surprising that up to 25% of patients had positive axillary nodes in that setting, and survival after radical mastectomy was about 75%.

A more accepted definition of in situ breast cancer is that complete histologic analysis shows no areas of invasion. In this setting, involvement of axillary nodes is seen in less than 1% of cases[10] and survival with no evidence of disease (NED) after mastectomy is close to 100%.

This study attempts to answer two questions seldom addressed in the past: What is the outcome of patients with in situ breast cancer followed up for more than ten years? Also, does careful pathologic review in patients with unusual findings (positive axillary nodes) or unexpected outcome after mastectomy (local recurrence, distant metastases) reveal microinvasion? Additional subgroups for analyses were those with predominantly in situ disease but with microinvasion and patients with bilateral breast cancer whose disease on the initial side was in situ.

PATIENTS AND METHODS

All patients treated for in situ breast carcinoma at Memorial Sloan-Kettering Cancer Center, New York, between 1970 and 1976 were analyzed. Patients were divided into those with pure DCIS, lobular carcinoma in situ (LCIS), or mixed DCIS-LCIS. Patients with previous carcinoma were excluded. Two hundred twenty-five patients were analyzed, but the study was restricted to patients with unilateral in situ breast cancer. Therefore, 42 patients with predominantly in situ cancer but evidence histologically of microinvasion were analyzed separately, as were 25 patients with bilateral breast cancer.

Long-term follow-up was stressed; of the remaining 158 patients, eight were excluded because their follow-up was less than five years. All were free of disease when last seen. Thus, a median follow-up of 11.5 years was achieved (range, five to 17.4 years).

RESULTS

Patients had DCIS in 85 cases, DCIS and LCIS in 22, and LCIS in 43. The indication for biopsy was usually a mass, which most often was not caused by these diseases. A mammogram was the indication for biopsy more often in patients with DCIS than with LCIS, but DCIS also presented as Paget's disease or nipple discharge. Mammography was not done often in this earlier series, but results were more often positive in patients with DCIS than with LCIS. Mammograms were suggestive in 49 of 55 patients with DCIS and ten of 14 with DCIS and LCIS. They were positive less frequently in LCIS (13 of 22), and

mammograms were less often the reason for biopsy in this group.

Treatment is listed in Table 1. The majority of patients underwent modified radical mastectomy (112 cases). Fifteen patients were treated by radical mastectomy, 18 by biopsy alone, and five by total mastectomy. No patient underwent radiation therapy or received systemic treatment. Histologic confirmation of axillary node involvement was seen in only one patient of 128 who underwent node dissection (modified radical mastectomy or radical mastectomy). Of the remainder treated by total mastectomy (five) or biopsy alone (18), none developed positive nodes. This confirms the infrequency with which axillary nodes are involved by noninvasive breast cancer.

The status of the patients is shown in Table 2. A total of six patients died of other causes, free of breast cancer at their last examination.

The one patient listed as having died of disease underwent modified radical mastectomy for microscopic DCIS. Axillary lymph nodes were negative pathologically, but two years later she presented with contralateral axillary metastases and parasternal recurrence. Biopsy specimens of both showed a similar histologic pattern of poorly differentiated infiltrating breast cancer. She died a few years later with distant metastases. Although we suspect she had a contralateral invasive breast cancer, it never manifested itself, and therefore she is listed as having died of DCIS. If one accepts this judgment, of 107 patients with DCIS in this series (85 with pure DCIS and two with DCIS and LCIS), 106 were free of disease.

Considering the limits of a retrospective study, some patients were selected by their surgeons (or were self-selected) to undergo no further treatment of in situ breast cancer after excision alone. In an era before wide excision or pathologic assessment of margins, these 18 patients fared well. Two developed ipsilateral breast recurrence (both six years after biopsy), and both had NED after modified radical mastectomy, with negative axillary nodes. Thus, all 18 patients were free of disease.

Patients with microinvasion represent an interesting subgroup, given pathologic difficulties in this assessment. In 42 such patients, all treated by mastectomy with axillary node dissection (Table 3), four (10%) had positive axillary nodes. This perhaps subtle microscopic finding carries a significant risk of regional spread. Three patients died of disease (39 [94%] had NED), indicating the need for accurate diagnosis. This is increasingly important with more DCIS cases being found by mammography.

The 25 patients who developed contralateral breast cancer were analyzed separately also, and all were free of disease. In all cases, the primary side had in situ carcinoma, and in 14, due to contralateral biopsy, bilateral in situ disease was diagnosed and treated. Of interest, eight patients developed metachronous invasive cancer, two with positive nodes requiring adjuvant chemotherapy. All patients had NED at this writing.

These results reflect changes in classification after pathologic review of six questionable cases (done by P.P.R.). Assuming that all patients with in situ disease should do well after mastectomy, questionable cases that were reviewed were those DCIS cases initially thought (1) to have positive axillary nodes (two cases); (2) to have died of disease (two patients); (3) to be alive with disease (one); and (4) to have NED after local recurrence (one patient). Five of these six were changed after this review, three due to unsuspected microinvasion, one for development of invasive cancer in the contralateral breast, and one after having died of disease.

The one patient listed as having died of DCIS had undergone modified radical mastectomy. No microinvasion was noted, and all axillary nodes were negative for recurrence. Four years later she developed contralateral axillary metastases and parasternal recurrence. Biopsy specimens of both lesions showed poorly differentiated invasive breast cancer, and she died of disease four years later. In all likelihood, she had a contralateral invasive breast cancer, but because it never manifested, she was listed as having died after treatment of DCIS.

COMMENT

Due to detection by mammography, breast carcinoma in situ, especially DCIS, is being seen in greater numbers than in the past.[11] In previous years, most patients with DCIS presented with a mass, Paget's disease of the nipple, or nipple discharge, as was true for this series (1970 through 1976). Lobular carcinoma in situ, without a characteristic mammographic pattern, continues to be seen in pathologic analyses of otherwise benign breast biopsy specimens.

The definition of DCIS has changed also. Haagensen[9] considered this disease to harbor invasive elements in virtually all cases, and the diagnosis of intraductal carcinoma was made if less than half the lesion had histologically invasive elements. This explained a high incidence of positive axillary lymph nodes in his series (29%) and a ten-year survival rate of about 70% after radical mastectomy. The same definition was apparently used by the American College of Surgeons survey,[8] with a similar rate of axillary

lymph node involvement and a comparable survival rate.

A more modern definition of in situ breast cancer (especially DCIS) eliminates patients whose carcinoma has any invasive components (even microinvasion); the entire histologic pattern is noninvasive.[10] When this definition is adhered to, mastectomy specimens will show unsuspected invasive carcinoma in approximately 5% of cases and pathologically involved axillary lymph nodes in less than 1% of patients.

A revised concept of DCIS has been proposed by Gump et al.[12] Gross DCIS is defined as those lesions presenting as clinical entities (mass, Paget's disease, or nipple discharge), whereas microscopic DCIS is those nonpalpable lesions detected by mammography or noted pathologically as incidental findings. When separated into these two groups, analysis of mastectomy specimens shows that gross DCIS carries a 13% incidence of multifocal microinvasion, and one of 52 patients had involved axillary nodes. Patients with microscopic DCIS had no coexistent invasive cancer and no positive nodes.

Lobular carcinoma in situ has not undergone similar changes in definition, principally because it never presented as a clinical entity and has no characteristic mammographic pattern.[13] Other important differences between DCIS and LCIS are (1) that LCIS has a more frequent bilateral expression and (2) that, when treated by excisional biopsy only, patients with LCIS develop ipsilateral breast carcinoma less frequently, and within a longer time frame, than do patients with DCIS.[14-16]

Previous series from this institution analyzing patients with in situ breast cancer have documented good results with mastectomy.[1,5,6,17] Only one patient with DCIS died of disease. Others died of other causes with NED or died of breast cancer after developing contralateral invasive cancer. However, follow-up was in the range of five years.

Sunshine et al[18] reported on 112 patients with in situ breast cancer followed up a minimum of ten years. Four patients died with metastatic disease (three with DCIS and one with LCIS). Excluding patients who died of other causes, the survival rate free of disease was 95% for patients with DCIS and 97% for those with LCIS. These authors found a high incidence of bilaterality and advocated bilateral mastectomy for patients with in situ breast cancer.

In our present series, only one of 150 patients had axillary metastases, and that a micrometastasis to one level I node. A complete axillary dissection accompanying total mastectomy is not justified if pathologic certainty of no microinvasion can be assured. Total mastectomy with removal of some lower axillary nodes near the tail of the breast is the treatment of choice. Immediate (or delayed) reconstruction can be carried out if patients wish. The avoidance of an axillary dissection in more modern series of microscopic DCIS is even more strongly recommended.[12,19]

Eighteen patients in this series did well after biopsy alone; two developed ipsilateral invasive carcinoma six years later and both underwent modified radical mastectomy, with axillary nodes negative. Both had NED more than 11 years later. The reason for selection of this management was not apparent, but apparently this approach may be successful. Whereas we have known this to be true for patients with LCIS, the outcome of patients diagnosed with DCIS treated by observation only, or excision plus radiotherapy, awaits results from trials[20] and longer follow-up.[21]

The finding that microinvasion in a predominantly in situ breast cancer carries a risk of axillary node metastases has been confirmed in other studies.[22,23] Axillary node dissection should be carried out in this setting, and also when the pathologic descriptions indicate that microinvasion cannot be ruled out. In the current series, careful pathologic review of six patients who had findings or outcomes unlikely related to pure in situ disease changed the final classification in five. Two patients said to have had DCIS and who subsequently died of disease were found to have had microinvasion in the breast. Both had negative nodes after modified radical mastectomy. Of two patients thought to have had DCIS with positive axillary nodes, one had microinvasion. One patient with DCIS, alive with metastases, developed a contralateral invasive cancer, probably the cause of the distant disease.

The last patient, the only one with DCIS to have died of disease, probably had contralateral invasive cancer, but because it was never established, she is listed as the one death. Four years after she underwent modified radical mastectomy for microscopic DCIS, with negative nodes, she presented with ipsilateral chest wall recurrence and contralateral axillary metastases. She underwent biopsy of both lesions, and poorly differentiated invasive breast carcinoma was diagnosed. Bilateral adrenalectomy led to regression, but she died of distant disease four years later. Although we suspect she had a contralateral invasive breast cancer, one never appeared clinically and she did not undergo autopsy.

Discussion

Q Did you separate your palpable cancers and those that were picked up by mammography?

A We do have them separated out. Most of the patients in this series had biopsy because of a mass. We do have ten with Paget's disease and 12 who presented with nipple discharge. Mammography was an infrequent indication for biopsy in the whole series.

Q Any explanation for such an excellent prognosis in the bilateral group even with metachronous invasive cancers?

A No; actually you could say our follow-up wasn't too good in that series, because the first side presented as in situ, and in eight cases they had metachronous invasive cancer, two with positive nodes. So maybe in that subset we didn't do so well, but they've all done well since.

Q What do you do for your second opinions who come to you with in situ disease in only one side?

A The common situation is that they probably have an abnormal mammogram, and we discuss the options for treatment with them. If it's DCIS I'm a little less comfortable than Dr Schwartz about a follow-up–only policy, but we would embark on that or a radiation policy in a patient interested in breast preservation. We would want a follow-up mammogram that shows no microcalcification and probably a reexcision to check for margins. The pathologist from Nimegan, Holland, has looked at a subset of patients with DCIS and mapped out how many centimeters away from the lesion multicentricity actually exists. His finding is that multicentricity is almost always within a quadrant. That, plus the Lagios data from San Francisco, leads us to believe that there probably is a subset of patients with microscopic DCIS in a small focus who want neither a mastectomy with immediate reconstruction nor radiation therapy and who are willing to accept a quadrantectomy. We will ink the margins and look very carefully for the presence of multicentric disease in that quadrant. I think this may be an in-between approach we're willing to embark upon. We're not going to have a large number of patients in a prospective study. We just can't do that. But this, to me, is a very rational approach to this disease for patients who understand why we're doing it and can't put up with the other two options.

There are lots of options in this society today. You can tell them about the National Surgical Adjuvant Breast Project trial. I haven't had too many who are interested in a computerized approach to how this disease is handled. We have a subset who understand that mastectomy is probably not necessary, but they feel that the peace of mind they gain with that, whether or not they have immediate delayed reconstruction, is worth it. They may have friends who have died of breast cancer. They may have a positive family history or other factors. That has to be offered to them as an option, obviously, and it doesn't include a node dissection in our hands for what is in situ disease. The node dissection we reserve for patients who are going to get treated by mastectomy or by radiation therapy, for those who have obvious microinvasion, or a smaller subset of patients in whom the most competent of our pathologists will say they cannot rule out microinvasion. That's a reason to do a low axillary lymph node dissection.

So we have basically two options that we offer the patients; it's a mastectomy or it's radiation therapy after all disease is out, with all the reservations that we and our radiation oncologists, frankly, have about the effects of radiation. Until studies like the National Surgical Adjuvant Breast Project reveal what happens to people who are untreated, we may be putting them at some risk. There's no doubt, in the little information we have from breast preservation approaches with radiation, that some of those recurrences both in the radiated breast or the nonirradiated breast are invasive carcinoma. So we're now taking a subset of patients who had a 100% cure rate with a mastectomy and we're allowing them to progress to invasive cancer with all that it means potentially for their prognosis, and I'm uncomfortable telling a patient that I think that.

Myofibroblasts in Head and Neck Surgery: An Experimental and Clinical Study

Wayne F. Larrabee, Jr, MD; John W. Bolen, MD; Dwight Sutton, PhD

Myofibroblasts in human granulation tissue have many of the structural and functional characteristics of smooth-muscle cells and appear to be responsible for wound contraction. They have also been identified in contracted scar tissue in nongranulation wounds. In this report, their role in head and neck wound healing will be explored utilizing transmission electron microscopy and immunoperoxidase techniques with antibodies to the intermediate filament vimentin and to muscle-restricted actins. In piglets, high-tension, low-tension, and granulating wounds were created and studied with serial biopsy specimens. Results showed few myofibroblasts in either the high- or low-tension wounds and multiple myofibroblasts in the granulating wounds. In the clinical studies, the immunoperoxidase technique with monoclonal antibody to muscle-specific actins proved most useful in identifying myofibroblasts. Myofibroblasts were present in granulating wounds and hypertrophic scars. They were not widely present in mature keloids (*Arch Otolaryngol Head Neck Surg* 1988;114:982-986).

Implications of Accurate Pathologic Margins in the Treatment of Primary Breast Cancer

Thomas G. Frazier, MD; Randolph W. Y. Wong, MD; David Rose, MD

• Eighty-seven patients who underwent mastectomy or reexcision following a previous segmental resection with pathologic margins evaluated at that time were restudied following their definitive therapy. Of these, 40 (46.0%) had involved margins, 28 (32.2%) had close margins, and 19 (21.8%) had clear margins. Residual tumor was subsequently found in 21 (52.5%) of 40, nine (32.1%) of 28, and five (26.3%) of 19, respectively. Analysis of specimens for quadrant of residual tumor showed 27 (31.0%) of 87 patients in the same quadrant, and 11 (14.7%) of 75 present in a different quadrant. The assessment of microscopic margins may be misleading since 29.8% (14/47) of patients with clear or close margins subsequently had residual tumor, and 47.5% (19/40) of those with involved margins had no residual tumor found. Further studies are essential to define the optimum guidelines for tumor excision at the time of segmental resection.

(*Arch Surg* 1989;124:37-38)

As primary radiation therapy has evolved to an acceptable option in the treatment of early breast cancer, the emphasis on segmental resection now focuses not only on favorable pathologic factors for primary radiation therapy but also on the optimum surgical technique to maximize survival and minimize local failure. This report seeks to evaluate the accuracy of our current methods of deciding on margins of resection and to explore further the incidence of multicentricity as it relates to the natural history of breast cancer.

PATIENTS AND METHODS

We reviewed 452 consecutive patients with breast cancer treated by the same surgeons (T.G.F. and D.R.). Two hundred sixteen (48%) had an excisional biopsy as their initial diagnostic procedure. After reviewing the clinical records and pathologic reports, 96 (44%) of these were stratified into one of two groups. Nine patients had original biopsies at other institutions and were not originally marked for margins and were therefore excluded from the study. Of the 87 remaining patients, 75 fell into group A, those patients who initially had excisional biopsy followed by modified radical mastectomy for local control. Twelve patients fell into group B, those patients who opted for segmental resection only but who underwent reexcision of their original biopsy site because of involved margins. The patients ranged in age from 33 to 85 years and had a mean age of 61.7 years.

All 87 patients had their original margin evaluation according to protocol B-06 of the National Surgical Adjuvant Breast Project.[1] The periphery of the specimen was stained with india ink. Margins were considered uninvolved if they were clear of the inked margin. They were considered involved if the tumor cells were within the inked borders or less than one high-power field away.

At the time of mastectomy or reexcision, multiple sections were taken to check for residual carcinoma. In the mastectomy specimen, random sections were taken from other quadrants and from any other suspicious areas as well.

RESULTS

Seventy-five patients (86.2%) had mastectomy for local control and 12 patients (13.8%) had reexcision. The distribution according to histologic type of tumor and nodal status is given in Table 1. As expected, infiltrating ductal carcinoma was the most common pathologic finding, and 25 patients (28.7%) had nodal involvement. Table 2 gives the pathologic results regarding residual tumors in the second-procedure specimens. Five (26.3%) of 19 patients with clear margins, nine (32.1%) of 28 patients with close margins, and 21 (52.5%) of 40 patients with involved margins had residual tumor. In the 75 patients with mastectomy, 11 (14.7%) had tumor foci in a quadrant separate from the original biopsy quadrant. Seven (63.6%) of these 11 had residual tumor in the same biopsy quadrant as well. Subsequent subset analysis showed no difference for age, histologic type of tumor, nodal disease, or hormone receptor analysis.

Table 1.—Histologic Features and Axillary Node Status*

Histologic Feature	No. (%)	Nodal Involvement, No. (%)
Infiltrating ductal	62 (71.3)	18 (29)
Infiltrating ductal and LCIS	8 (9.2)	4 (50)
Lobular	4 (4.6)	1 (25)
Medullary	3 (3.4)	0 (0)
Infiltrating ductal and infiltrating lobular	2 (2.3)	1 (50)
Infiltrating lobular and LCIS	2 (2.3)	1 (50)
Mucinous	2 (2.3)	0 (0)
Other	4 (4.6)	0 (0)
Total	**87 (100)**	**25 (28.7)**

*LCIS indicates lobular carcinoma in situ.

Table 2.—Residual Tumor at Reexcision or Mastectomy

Margins	No. (%)
Involved	21/40 (52.5)
Close	9/28 (32.1)
Clear	5/19 (26.3)
Total	**35/87** (40.2)

COMMENT

Logically, the complete excision of a tumor is not only desirable from a therapeutic standpoint but is also desirable from the standpoint of a lower local recurrence rate than are incomplete excisions.[2,3] The question remains, however, as to how much tissue is actually required to assure complete removal. Studies have ranged from removal of a complete quadrant and underlying fascia[4] to gross removal with only a small rim of normal tissue.[5] Since the publication of the initial results of protocol B-06 of the National Surgical Adjuvant Breast Project,[1] surgical margins that are microscopically free have become the benchmark for comparison, since this was a truly randomized prospective clinical trial. Although numerous reports have expressed the difficulties encountered in assessing margins,[6] no one heretofore has correlated the margins with residual disease. These results underscore the difficulty associated with margins that are close or involved, making the job of the pathologist extremely difficult; equally impressive is the fact that over one fourth of those patients with clear margins had residual tumor present. Of significance as well was the finding that even in patients with margins involved, residual tumor was found only half of the time. This raises a number of issues for consideration: (1) Should a much wider area of resection be an integral part of planning in the segmental resection? (2) Are gross margins as evaluated by the operative surgeon satisfactory for breast conservation surgery? (3) Should every patient receive a "boost" of x-radiation to the segmental site or the quadrant involved? (4) What tumor factors will predispose the patients to a high likelihood of residual disease, and should these factors influence initial treatment toward total mastectomy?

Obviously, these and other questions can only be answered by greater experience and further subset analysis of the various pathologic and tumor factors. Such approaches might include flow cytometry, nuclear grading, and other pathologic criteria. Until such criteria are developed, however, the present standard of microscopically free margins should continue, but serious consideration to a local boost must be given in each patient undergoing less than mastectomy for local control.

Discussion

Q For the future, would you consider research directed at better assessment of margins?

A I think I would. I would be interested to hear what some of the pathologists in the room have to say about that because I think this is very difficult. I think sometimes we lean too heavily on what the pathologists tell us in terms of the margins.

Q Has anybody found a foolproof method for an accurate margin assessment?

A I am not a pathologist. I do not see how you could be sure, when you are doing your reincision, that there is no residual tumor. The way we do our reexcisions is to actually take the scar and take out the whole biopsy cavity. Some people reexcise only that portion of the segmental site where the margins were close or involved. They go in through the same scar. It really varies from person to person. The way we did all of our reexcisions was to reexcise the scar and the entire biopsy cavity and ink that.

Q When these were done using local anesthesia, did you find any difference in how the biopsy was done?

A They were really done half and half. The mode of initial resection did not seem to matter. They were all prepared and sent to the pathologist in the same fashion.

Q Did not the Joint Center for Irradiation have the same problem and find that the amount of residual disease in the breast on reexcision could be predicted by the extent of intraductal carcinoma in the original biopsy specimen?

A We did not find that to be a parameter. I think that needs to be looked at. Again, this is a small series, and I would hope that some of the people at Memorial and M. D. Anderson, which have much larger series, would look at this.

A I would like to make a suggestion, since we are more interested in what we leave behind than what we take out. After we have done a so-called lumpectomy, we then take specimens from what we would be leaving behind and very carefully clip those with small clips. We send specimens from four to six places to the surgical pathologist and have him separately mark those as the margins past the lumpectomy site. The clips that we leave very clearly mark those sites for the radiation oncologist.

Q I hate to be a spoil sport, but does any of this have anything to do with outcomes?

A No. Not yet, anyway.

Q Are we becoming so preoccupied with process that we forget why we are doing what we are doing? The idea of knowing whether the margins are free really depends to some degree on fastidiousness and less on luck. Yes, we dip the whole thing in ink with a biopsy specimen if we know that the surgeon is not going to follow this immediately with a mastectomy. We do leave the whole borders and make a determination not on frozen section but on paraffin section if there is not to be a mastectomy immediately.

There are data to show that diffuse intraductal carcinoma within the tumor or intraductal carcinoma away from the tumor within the biopsy site are predictors of failure of excision with radiation therapy. So marginal involvement is information worth having. But with the business of finding that so many with tumor in the margin of the resection had no tumor in the mastectomy, a lot depends on the effort put into the reconstruction. When you get right down to it, the biology of this seems to me to be more important than the process. When we think about noninvasive cancer of the breast, we have no way of measuring at what point we have interrupted that process. The fact that there are multiple foci in some patients, and few foci in others, may reflect the fact that in the one with one or two ducts involved we have interrupted the process at an earlier phase and in the other we have interrupted it at a more advanced phase.

So to say that one or two ducts involved means that you do not have to do anything about it would be answered only with time. Even when that breast is removed for a few ducts of intraductal carcinoma and nothing is found, how do we know what would have been there six months, two years, or three years later had we left that breast? So I think that we are pushing back the frontiers of knowledge, but we still need time to answer some of these questions. I would make a plea that if there are going to be attempts to answer the questions by withholding treatment that this be done in a context of a clinical trial so that after a time, we will be able to answer the question. It is, I think, very important to embark on therapeutic programs that can be measurable so that we can adjust what we are doing by scientific information.

Lability of Steroid Hormone Receptors Following Devascularization of Breast Tumors

Lee M. Ellis, MD; James L. Wittliff, PhD; Michael S. Bryant, MD;
Harry S. Sitren, PhD; William E. Hogancamp; Wiley W. Souba, MD, ScD; Kirby I. Bland, MD

• Ischemia may invalidate hormone-receptor analyses. This study determined the effects of progressive ischemia on steroid hormone–receptor analyses. Breast cancer was induced in 50- to 60-day-old female Holtzman rats by intragastric administration of 25 mg of 7,12-dimethylbenz[a]antracene. After 90 days, rats were anesthetized and breast tumors were devascularized in vivo. At 0, 30, 60, 90, and 150 minutes, a biopsy specimen from each tumor was taken and rapidly frozen. Steroid binding capacity for estrogen (ER), progesterone (PR), and androgen (AR) receptors was determined by incubation with tracer receptor ligand. Ischemia decreased ER and AR levels by 30 minutes, whereas PR levels were unchanged through 150 minutes of ischemia. Following mastectomy, tylectomy, or breast biopsy, PR may be the most reliable of the hormone receptors for determining endocrine-responsive breast cancer. However, for accurate determination of all hormone receptors, specimens should be frozen in liquid nitrogen immediately, then preserved at −70°C, or processed immediately.

(*Arch Surg* 1989;124:39-42)

Quantification of steroid hormone–receptor levels in breast cancer now plays an integral role in selecting patients for hormonal therapy.[1-9] If both the estrogen receptor (ER) and the progesterone receptor (PR) are positive, nearly 80% of patients will demonstrate an objective response to hormonal therapy.[1,8] Conversely, if the ER is negative, fewer than 10% of patients with breast cancer will respond to endocrine manipulation.[1,8] Recently, the androgen receptor (AR) has also been found to be predictive of endocrine-responsive breast cancer.[10,11] Therefore, it is imperative that accurate steroid hormone–receptor analysis be performed to manage the patient with breast cancer properly. However, since steroid hormone receptors are labile cytoplasmic proteins, the conditions for procurement and processing of tissue for analysis may be critical for accuracy and proper interpretation. Several studies have noted a decrease in ER content in mastectomy specimens compared with biopsy tissue from the same patient.[12-14] This discrepancy may be due, in part, to surgically induced ischemia during mastectomy.

It is generally recommended that tissue be frozen within 30 to 45 minutes following surgery.[8] However, the period from devascularization of the specimen to surgical excision may further lengthen the period before proper tissue preservation. This period may allow for significant receptor autolysis, and thus may render a false-negative analysis. This study was conducted to determine the effects of progressive ischemia on sex steroid hormone–receptor analyses in an experimental breast tumor model.

MATERIALS AND METHODS

The 7,12-dimethylbenz[a]antracene (DMBA) chemically induced breast cancer in rats was chosen as the tumor-host system. The majority of these tumors are hormonally dependent and thus serve as a model of endocrine-dependent breast cancer.[15,16] Additionally, in a review of experimental breast cancers, Hilf[17] stated that DMBA-induced breast carcinoma and human mammary carcinoma are similar with regard to various metabolic processes. McGuire and DeLaGarza[18] noted a strong similarity between ERs in human breast cancer and the experimental rat mammary model. Therefore, this experimental host-tumor system serves as an appropriate model for human breast cancer.

Female Holtzman rats, 40 to 50 days old, were housed four to a cage under constant temperature (25°C to 30°C) and with a 12 hour/12 hour light-dark cycle. They were fed tap water and stock chow (Purina Rodent Chow) ad libitum.

Experimental Protocol

At 50 to 60 days of age, rats were lightly anesthetized by halothane exposure. Fifteen milligrams of DMBA dissolved in 1.5 mL of corn oil was administered by intragastric intubation. One week later, 10 mg of DMBA was given in a similar fashion. Ninety days later, rats were anesthetized with ketamine (50 mg/kg intramuscularly). Tumors were then sharply enucleated in vivo without the use of cautery or instillation of chemicals, and the skin was approximated over the tumor with clamps. The procedure was designed to simulate mastectomy. At 0, 30, 60, 90, and 150 minutes, a viable biopsy specimen was taken from each

tumor and rapidly frozen in liquid nitrogen. Euthermia was maintained (37°C to 37.5°C) during anesthesia. Tumors were stored at −70°C before shipping and analyses.

Analytical Methods

Tissues were packed in dry ice and forwarded to the Hormone Receptor Laboratory, James Graham Brown Cancer Center, University of Louisville, for ER, PR, and AR assays.

Sample Preparation.—At the time of tissue assay, conducted two to three weeks after tissue procurement, tissues were rapidly thawed at 4°C and homogenized in cold buffer (10 mmol/L of TRIS hydrochloride) containing 1.5 mmol/L of edetic acid, 10 mmol/L of monothioglycerol, 10% glycerol (wt/vol), and 10 mmol/L of sodium molybdate (pH, 7.4) with two to four 10-s bursts using an electronic homogenizer (Ultra-Turrac 18/10 shaft 10 N). Cytosol (supernatant) was prepared by centrifugation of the homogenate at 105 000 g for 30 minutes at 4°C. Protein level was determined by the method of Bradford[19] utilizing bovine serum albumin as a standard. All subsequent procedures were performed in an ice-water bath.

Quantification of Steroid Hormone Receptor Profiles.—To determine affinity and concentration of steroid hormone receptors in the cytosol preparations, aliquots (0.1 mL) were incubated overnight (16 to 18 hours) at 3°C with six increasing concentrations of either tritiated estradiol-17β (3 to 0.15 nmol/L) for ERs, tritiated R5020 (8 to 0.4 nmol/L) for PRs, or tritiated mibolerone (6 to 0.5 nmol/L) for ARs in 0.05 mL of TRIS buffer with or without a 200-fold excess of unlabeled inhibitor. Assays were conducted as described by Bland et al[20] using the inhibitors described for each receptor.

Statistical Analysis

Results were standardized by defining the value at baseline as 100% (control). Corresponding values at the later periods were then expressed as a percent of control. Statistical analysis was performed by two-way analysis of variance with significant differences occurring at the 95% confidence interval. Treatment means were compared with controls.

RESULTS

Of the 18 rats (approximately 80%) developing mammary tumors, 11 tumors were selected for study based on tissue integrity, size, and growth properties. Nearly 80% of these rats had multiple tumors. However, only one tumor from each rat was used for analysis.

The Table shows that ischemia significantly decreased ER levels within the first 30 minutes ($P = .05$). The ER values remained decreased throughout 150 minutes of ischemia. Similarly, AR levels were significantly lower by 30 minutes of ischemia ($P = .002$) and remained so throughout 150 minutes. The largest decrease in ER and AR levels occurred within the first 30 minutes of ischemia. In contrast, PR levels were unchanged throughout 150 minutes.

Mean (±SEM) values at baseline for ER, PR, and AR were 70 ± 10, 149 ± 34, and 20 ± 2 femtomoles/mg of cytosol protein, respectively.

To determine the half-life of these hormone receptors under these experimental conditions, the receptor values were plotted logarithmically as a function of time. By this method, the half-life of the ER was approximately 175 minutes and that of the AR was approximately 50 minutes. The half-life of the PR could not be accurately calculated in this system due to its stability in regard to ischemia over this period. It is apparent that the half-life is substantially greater than that of the other hormone receptors using this tumor model.

COMMENT

Determination of tissue steroid hormone–receptor levels is now a routine and necessary procedure in the management of breast cancer. A plethora of clinical investigations have reported the use of steroid hormone–receptor analysis in predicting hormonal responsiveness as well as survival.[1-9] To effectively utilize knowledge of the tissue concentrations of these labile proteins and assure reproducibility, standardization of assay techniques must be established. Quality control was initiated in the Hormone Receptor Laboratory at the University of Louisville in 1978.[8] However, due to the lability of these cytoplasmic proteins, variation in surgical techniques and in preservation techniques may affect receptor analysis. Several comparative studies have documented a decrease in hormone-receptor levels from biopsy specimens vs mastectomy specimens.[12-14] These observations prompted this investigation on the effects of progressive ischemia on steroid hormone–receptor levels. Theoretically, a prolonged surgical procedure or a delay in proper preservation of tissue may invalidate steroid hormone–receptor analysis. Thus, an individual with breast cancer may falsely be labeled hormone-receptor negative. This patient, with a false-negative result, may not receive optimal adjuvant therapy.

Steroid Hormone Receptor vs Ischemic Time*

	Ischemic Time, min				
	0	30	60	90	150
ER (n = 11)	100	79 ± 10†	67 ± 11†	54 ± 11†	56 ± 13†
PR (n = 11)	100	101 ± 21	101 ± 26	94 ± 14	84 ± 27
AR (n = 11)	100	57 ± 12†	53 ± 15†	28 ± 9†	42 ± 12†

*Values are mean ± SEM, expressed as percent of control at baseline. ER indicates estrogen receptor; PR, progesterone receptor; and AR, androgen receptor.

†$P \leq .05$ compared with baseline by analysis of variance.

The present study was designed to simulate mastectomy. Tumors were enucleated in vivo and core body temperature was maintained. Furthermore, this study was also similar to other studies examining receptor levels from biopsy specimens and from completion mastectomy. In the present study, results obtained were similar to those of several other studies[12-14] in that ER content was decreased at the termination of the procedure. Our study demonstrated a marked decrease in ER and AR content in the first 30 minutes.

It should be noted that the ERs and PRs may be occupied by endogenous hormones, since the experiment was conducted in animals with intact ovaries. It is known that in the absence of ligand, these receptors are even more labile, as would be the case in the postmenopausal patient with breast cancer. Therefore, it is possible that in postmenopausal patients with breast cancer, the hormone receptors may undergo autolysis at an even greater rate. The PR content was maintained throughout 150 minutes of ischemia. Other investigators have noted that the PR may be the more sensitive of the steroid hormone receptors in predicting hormonal responsiveness.[3,6,7] Fisher et al,[7] in a randomized prospective study of 1891 patients with breast cancer on the National Adjuvant Breast and Bowel Project, found that the PR tumor content was a stronger predictor than the ER content in predicting response to cytotoxic chemotherapy plus tamoxifen. Osborne et al,[3] in an earlier study of 65 patients, found that the presence of the PR may be a better predictor of hormonal responsiveness than the quantitative value of the ER. Clark et al[6] stated that the PR value may be of equal or greater value than the tumor ER content in predicting disease-free survival. These findings may be due, in part, to "false-negative" interpretation of ER levels secondary to surgically induced

ischemia or improper tissue preservation, inasmuch as the ER appears more susceptible to ischemia and autolysis than the PR.

Several investigators have studied the levels of the steroid hormone receptors in biopsy specimens and from subsequent completion mastectomy specimens. However, there is no general consensus in regard to the validity of receptor analysis in the mastectomy specimen. Young et al[14] compared ER levels in biopsy and mastectomy specimens from 58 patients. They found a 44% false-negative ER determination in the mastectomy specimen. They also noted that 13 (42%) of 31 patients who were ER positive at mastectomy had at least a 50% drop in the ER level when compared with the level found at biopsy.

Newsome et al[13] found a 15% to 100% (mean, 70%) decrease in ER levels in completion mastectomy specimens when compared with biopsy specimens. It was concluded that the decrease in ER levels is inversely proportional to the period from devascularization to freezing. They speculate, as do we, that the ER-negative patients who respond to hormonal therapy may represent inadequate sample procurement. Hassan et al[12] in a similar study found that ER levels were 1.6 to 6.5 times greater in the biopsy specimen than in the mastectomy specimen.

In contradistinction, several authors have concluded that the mastectomy specimen *is* adequate tissue for receptor analysis. Leight et al[21] in studying biopsy and mastectomy specimens from 21 patients concluded that the biopsy specimen is preferred to the mastectomy specimen but that tissue from a properly handled mastectomy specimen is satisfactory for receptor analysis.

Meyer et al[22] studied 71 cases where biopsy and mastectomy specimens were available. They found a small significant reduction in the ER-positive assays in the mastectomy specimen compared with the biopsy tissue. They found no difference in the PR levels between tissues. Despite noting that false-negative ER interpretations may occur, they concluded that "significant losses do not occur" following completion mastectomy.

Inconsistent conclusions from these studies may be due to several factors. First, as in our study, the initiation of ischemia may affect receptor levels. However, variation in surgical technique, including the use of electrocautery, may cause variations in the degree of ischemia induced. Second, instillation of various chemicals into the wound, such as saline, water, alcohol, or betadine, may also alter receptor levels. Furthermore, there is a variable amount of tumor heterogeneity in regard to receptor concentrations. Most of the previously mentioned studies had too few patients to overcome this problem. The value of the present study is in the fact that only one variable was tested, namely, ischemia.

Bridges et al[23] studied levels of the ERs and PRs as well as their positivity in 131 women with breast cancer. Patients were divided into three groups: group 1 underwent biopsy followed by mastectomy with receptor being determined in the biopsy specimen; group 2 underwent modified radical mastectomy (MRM) in continuity with axillary dissection; and group 3 underwent en bloc mastectomy with tissue procurement within 15 to 20 minutes after the onset of surgery with axillary lymph node dissection performed separately following mastectomy. The frequency of ER and PR positivity was 72% and 40% following biopsy, 68% and 49% following MRM, and 89% and 64% following en bloc mastectomy, respectively. Although not statistically significant, the receptors showed a trend toward higher levels in the en bloc mastectomy specimens with rapid tissue procurement. Of note is the fact that the patients who underwent biopsy were younger than the other two groups. Regardless, when comparing the two mastectomy groups, these data suggest that rapid procurement of breast cancer specimens may allow for more accurate quantification of steroid hormone–receptor levels. However, these authors state that tissue from mastectomy specimens, if kept cold and rapidly frozen, may still be reliably used for quantification of the hormone receptors. Nonetheless, it is generally held that rapid and efficient procurement and processing of tissues is necessary for accurate hormone-receptor analysis.[8] To our knowledge, this is the first study elucidating the period over which ischemia affects breast tumor steroid hormone–receptor levels. Procurement within 30 minutes following devascularization is necessary to obtain accurate quantification of all three steroid hormone receptors.

At present, AR levels are not routinely analyzed or utilized in managing patients with breast cancer. However, several clinical studies suggest that knowledge of the quantitative value of AR may enhance prediction of those patients likely to respond to endocrine therapy.[10,11] If this holds true, then accurate determination of AR levels in neoplastic tissue is imperative.

In this experimental model, ischemia decreased ER and AR levels after only 30 minutes, whereas PR levels were maintained throughout 150 minutes. To obtain accurate analysis of all three steroid hormone receptors, tissue samples should be obtained before devascularization. Certainly, following breast biopsy, a portion of the specimen should be preserved for hormone-receptor analysis. It remains to be determined if biopsy of tissue just before mastectomy (and devascularization) should be obtained for hormone-receptor analysis rather than analyzing the mastectomy specimen itself. In circumstances where the PR is positive, yet the ER and/or AR are negative, consideration of the sensitivity and stability of the PR should be evaluated. In such a circumstance, false-negative values may have been obtained for the ER and/or AR, and the patient potentially may benefit from hormonal therapy.

We thank Marjorie McGarva and Cheryl Turner for preparation of the manuscript.

Discussion

Q Were you able to account in any way for possible effects due to the anesthetic?

A It is known that aberrations in the circulating hormone levels may alter receptor analysis. The ER level differs in premenopausal and postmenopausal patients and also differs according to the phase of the menstrual cycle; however, we do not have any evidence to show that ketamine or halothane, the two agents that we use, alter circulating hormone levels, but they may. However, these tumors were devascularized at time zero, so theoretically no blood flow should have been going to the tumor, affecting hormone levels.

Q Are you sure that this decrease in cytoplasmic receptor is not really a manifestation of an increased nuclear receptor? You were measuring essentially the cytoplasmic receptor. Studies done with electrocautery have shown that when you cauterize a specimen, the receptor is actually driven into the nucleus. Is it possible that the decrease you saw in your cytoplasmic determination with time is a similar event, due to ischemia or temperature or a variety of other factors that you have not controlled for?

A That may be true. We may not be measuring the true ER in that whole cell. However, the majority of laboratories do measure the cytoplasmic ERs or PRs, and if we are trying to make the study clinically applicable, I think that is where it holds true. If you measure nuclear receptors, they may be increased relative to controls; we did not do that.

Q Did you do monoclonal antibody studies?

A We did not do the study with monoclonal antibodies. I did happen to review the literature on comparison of monoclonal antibody studies vs standard methods of hormone-receptor analyses before this meeting in which there were a couple of studies looking at the effects of heat lability. The dextran-coated charcoal method and monoclonals were just as likely to find decreased levels with increasing temperature. There are no studies comparing ischemic time.

Q I think your findings are very important in view of a paper presented this morning with 1500 patients in the Scottish trial of tamoxifen. In their postmenopausal patients, ER-negative patients showed a highly significant effect of adjuvant tamoxifen. Those of us who follow these receptor studies usually quote an incidence of less than 10% for those patients who respond. However, I think this may be due to difficulty with the assay. Is this a metastasizing tumor model? If so, how do the metastases correlate with your initial receptor data?

A Over a longer period, you may have lymph node metastases. However, there were no apparent metastases at 90 days, and the amount of tissue that would be involved would not be enough to do assays.

Q Your analysis implies that there was variation between tumors. Did you also look at variation or heterogeneity within the tumor?

A We did. We took some control tumors and took five specimens from each tumor for assay. The coefficient of variation was about 30% for heterogeneity for all of the tumors. We originally had planned to use 25 tumors to try to cover for that large variation; however, due to necrosis and a tumor yield of approximately 80%, we only came up with 11 tumors for final analysis.

Age, Sex, and Race Inequality in Renal Transplantation

Carl M. Kjellstrand, MD

We calculated the chance of receiving a kidney transplant in the United States in 1983, and in the Midwest from 1979 through 1985, considering age, sex, and race. In the United States, 23 026 patients began long-term dialysis and 6112 (27%) received a kidney transplant. Transplant rates were 31% for men and 21% for women. White patients had a 30% rate and nonwhite patients a 20% rate. Patients less than 11 to 35 years old had an 85% rate vs a 3% rate for those older than 56 years. When race, age, and sex were analyzed together, nonwhite patients aged 21 to 45 years had only half the chance of receiving a transplant compared with white patients of the same age and sex. Women aged 46 to 60 years had less than half the chance of receiving a transplant when compared with men of the same age and race. These data show that there are age, sex, and race imbalances in the distribution of renal transplantation. We believe these imbalances only partially have a morally neutral biological, medical, social, and cultural explanation and that there should be a fairer distribution of kidney transplants (*Arch Intern Med* 1988;148:1305-1309).

Cancer Centers—Origins and Purpose

The James Ewing Lecture

William W. Shingleton, MD

• Cancer centers in the United States date back to the beginning of this century, although there were few until the late 1950s and 1960s. The National Cancer Act of 1971 introduced a new era in serving as a major stimulus to the development of comprehensive cancer centers. Research scientists and physicians in centers have contributed significantly to the new knowledge of normal and abnormal regulation of cell growth and differentiation and to the advances in the diagnosis and treatment of cancer. The future for cancer centers is very bright. They will continue to play a major role in the advancement of knowledge about cancer. However, centers must be reevaluated at intervals to correct any deficiencies and to stimulate new and innovative approaches. Surgical oncologists should become more involved in cancer center research. Comprehensive cancer centers should develop more effective regional cancer control and prevention programs. Reevaluation of centers by the National Cancer Institute, Bethesda, Md, and its advisory body, the National Cancer Advisory Board, along with cancer center leaders, should result in a consensus concerning changes to enhance their contribution to a solution to the cancer problem.

(*Arch Surg* 1989;124:43-45)

It has now been 17 years since the passage of the National Cancer Act of 1971. One section of the act authorized the establishment of 15 new cancer centers in the United States. Three years later, at the time the act was renewed, the ceiling on the number of such centers was removed. A number of questions have arisen concerning the purpose and accomplishment of these new and previously existing cancer centers. Are there unique features about cancer centers that enhance the ability of scientists in these centers to reach a solution to the cancer problem more effectively and rapidly? What has been the pattern of their development over the years relative to goals and purpose, organizational structure, and source of funding? What has been the impact of centers on the care of patients with cancer? How well have they accomplished their mission?

Accepted for publication July 6, 1988.

Dr Shingleton is Professor Emeritus at Duke University Medical Center, Durham, NC.

Read before the Annual Meeting of the Society of Surgical Oncology, New Orleans, May 24, 1988.

Reprint requests to Duke Comprehensive Cancer Center, Box 3814, Duke University Medical Center, Durham, NC 27710 (Dr Shingleton).

In an effort to answer some of these questions, this article will present, in an abbreviated fashion, (1) a historical perspective on the development of cancer centers, (2) a description of types and organization of centers, (3) the impact of the National Cancer Act of 1971 on the development of comprehensive cancer centers, and (4) some comments on problems, accomplishments, and future outlook for centers.

HISTORICAL BACKGROUND

Several categorical institutes devoted to a study of the cancer problem were established at the turn of the century.[1(p12)] The Roswell Park Memorial Institute, Buffalo, a state-supported institution, dates from 1898. A research program in cancer was inaugurated in 1906 at Memorial Hospital for the Treatment of Cancer and Allied Diseases, New York, and expanded in 1939 to become the Memorial Sloan-Kettering Cancer Center, New York. The University of Texas M. D. Anderson Cancer Center, Houston, was established in 1941 by an act of the state legislature. The American Oncologic Hospital, Philadelphia, was founded in 1904, and the Lankanau Research Institute, Philadelphia, was founded in 1925; these institutions have evolved into the present-day Fox Chase Cancer Center in Philadelphia. The Children's Hospital Research Foundation, established in 1947, was the forerunner of the present Dana-Farber Cancer Center in Boston. It is to be noted that these early institutions were funded initially either by private funds, state funds, or a combination of both. Several other privately supported categorical cancer institutes (later referred to as centers) originated in the 1950s and 1960s. These include St Jude's Children's Research Hospital in Memphis, Fels Institute in Philadelphia, the Michigan Cancer Foundation in Detroit, and the Institute of Cancer Research of Columbia University in New York.[1(p13)]

The first federally supported cancer research laboratory began operation in 1922 in the US Public Health Service.[2(pix)] The National Cancer Institute (NCI), Bethesda, Md, was established in 1937 by an act of Congress, the first institute of the later National Institutes of Health (NIH).[2(p13)] The earliest government contract funding for biomedical research in universities originated during World War II. This was followed soon after the war by the award of Public Health Service research grants to individuals,

administered by the NIH (Palmer Saunders, PhD, oral communication, April 1988). The NIH Clinical Center, Bethesda, Md, was dedicated in 1953, with each institute assigned a specific number of beds for research.[1(p1)] One of the most important features of this clinical center was the close collaboration that developed between laboratory and clinical research scientists. It has been stated that this center served as a prototype for later NIH support of clinical research in university medical centers.

The first extramural grant support program to universities for clinical research was initiated in 1960, and it was known as the Clinical Research Centers Program.[1(p2)] This policy reflected the addition of institutional research funding to the already established individual investigator-initiated research grant program. There were 19 funded university clinical research centers by the late 1960s. According to Walter et al,[1(p2)] there was a lack of sufficiently funded cancer research beds in these clinical research centers for cancer clinicians to participate effectively in NCI clinical cooperative studies. This resulted in the development and funding by the NCI of a Clinical Cancer Centers Program. The Health Research Facilities Grant Program of the NIH, which was available at that time, aided in the construction of facilities for these clinical cancer centers. The Program Project Grant (PO-1), the Cancer Clinical Research Center Grant (PO-2), and the Cancer Center Core Grant (P-30) were soon added as new mechanisms to support research in these centers. By 1963, there were 12 funded clinical cancer centers.[1(p3)]

Pertinent to these developments was the passage by Congress in 1965 of an act that established a Regional Medical Program to address the problems of heart disease, cancer, and stroke. The intent of this legislation was to organize regional community support for the earlier application of current research knowledge into medical practice related to these chronic diseases. These objectives, as related to cancer, were inadequately realized.[1(p3)] However, funds from this program helped to establish an NCI Planning Grant Program for cancer centers. These grants provided seed money for individuals at universities and not-for-profit institutions to work together in developing a cancer center. A number of institutions were successful in developing a cancer center as a result of these grants.[1(p3)]

The most important additional event that contributed to the further growth and support of cancer centers was the passage of the National Cancer Act of 1971. One section of this act authorized the director of the NCI to "provide for the establishment of fifteen new centers for clinical research training and demonstration of advanced diagnostic and treatment methods relating to cancer.[3(p103)] A conceptual basis for establishing these centers can be found in the summary statement of the Report of the National Panel of Consultants on the Conquest of Cancer that was prepared for the Committee on Labor and Public Welfare of the US Senate. Benno Schmidt, chairman of the panel, presented the summary recommendations of the report in testimony before this Senate committee in early December 1970.[8(p253)] The report called for passage of congressional legislation to establish a "National Program for the Conquest of Cancer," with provisions calling for additional funding of cancer research.[4] The pertinent section of this report, related to centers, stated the following:

> Existing cancer centers should be strengthened and additional cancer centers in different parts of the country should be created. The solution to the cancer problem lends itself to a multidisciplinary effort, where teams of highly qualified specialists are available to interact on problems of research, both clinical and non-clinical, teaching, diagnosis, prevention programs, and the development of improved methods in the delivery of medical care, including rehabilitation. Among those who work in the cancer field there is great emphasis on the advantages of a critical mass—a critical mass of scientists and physicians committed to the cooperative solution of the cancer problem, of research facilities, of patients, and of financial and other resources. This is simply another way of saying that the comprehensive cancer center offers the best organizational structure for the expanded attack on cancer.

Since passage of the National Cancer Act of 1971, 21 comprehensive cancer centers have been established; 20 currently remain. The emphasis in these centers has been to foster a multidisciplinary approach to cancer research and patient care, to provide a focal point for public awareness of the cancer problem and the need for support of research, to serve as a regional base for cancer control and prevention activities, and to develop organized support programs for patients with cancer. A majority of these centers are based in or allied to university medical schools.

TYPES OF CENTERS

Cancer centers can be classified in a variety of ways. A center may be classified according to a stated purpose or goal, organization, or source of funding. The major objective of some centers is to conduct basic biological laboratory research, and of others, primarily clinical research. Some of these "specialized" centers have both activities. Comprehensive centers, in addition to basic laboratory and clinical research, have programs in cancer epidemiology, cancer control and prevention, research training, and community outreach activities, including public and professional information and education. A center may be classified relative to organizational structure, ie, as freestanding, joint venture, departmental, matrix, or consortium. Based on the primary source of funding, they may be classified as federal, state, private, or a combination of these sources.

At the present time, there are 57 centers that have NCI-funded core support grants.[5] Two of the 20 comprehensive centers are the consortium type. A consortium center is one in which several medical schools participate. Fifteen of the comprehensive centers are associated with private universities, and five are associated with state-supported institutions. Twenty-five of the 37 specialized centers are clinical, and 12 are laboratory/basic; 30 are university associated, and seven are freestanding.

COMMENT

One of the problems related to cancer centers has been to define what constitutes a "center." This difficulty has led to some confusion on the part of both the public at large, as well as the scientific community. In my opinion, a center is best defined, in general terms, as being composed of a multidisciplinary group of research scientists and/or physicians who are bound together with a unity of purpose, who share concepts, facilities, and other resources, and who have developed an organizational structure that fosters effective management practices to achieve the desired goals of the group. Initially, there was considerable debate concerning the term *comprehensive* as applied to cancer centers. To attempt to satisfy the language related to centers present in the National Cancer Act of 1971, the NCI, with the advice and approval of the National Cancer Advisory Board, determined that there should be a group of centers that would have a broad approach to the cancer problem, including research, clinical care, prevention, and community outreach, with a precise organizational structure, and that these centers would be recognized by the

NCI as "comprehensive cancer centers."[1(p9)] A list of ten requirements was developed initially for the purpose of characterizing a comprehensive center. These were later modified and condensed to six requirements that are still in current use.[6] These requirements are, in abbreviated form, as follows: the center should (1) have an NCI-funded Cancer Center Support (Core) Grant; (2) possess a high-quality research program in laboratory, clinical, epidemiologic, and evaluative research that exists in an environment conducive to a collaborative effort among basic and clinical disciplines and epidemiologists, and with the participation by clinical scientists in regional and/or national clinical trials; (3) serve as a focal point for local and regional programs to control cancer through research activities in areas, such as prevention, detection, diagnosis, treatment, and rehabilitation; and (4) serve as a focal point for local and regional information, as well as lay and professional education programs, and possess a training program for professional and support personnel. The center should also (5) have a formal commitment of support from the parent institution indicating that the center director has (*a*) control of designated space and equipment, (*b*) necessary control over staff appointments, (*c*) control of grouped beds and ambulatory facilities, and (*d*) responsibility for planning, preparation of budgets, and development of an administrative structure that will assure sound management practices. Finally, the center should (6) have a geographic impact to assist the national capability to conduct regional trials, regional cancer control programs, and regional training, education, and information activities.

The scope of activities in comprehensive centers is somewhat variable from center to center due to the fact that some centers have emphasized certain activities and de-emphasized others. A reevaluation of comprehensive cancer centers by the NCI and the National Cancer Advisory Board is in progress at the present time.[7] The following questions are under discussion: (1) What has been the major accomplishment of cancer centers to date? (2) How many comprehensive cancer centers should there be in the United States? (3) Should these centers be geographically located? (4) How can "comprehensiveness" of a center be evaluated? (5) How should centers be funded in the future? (6) To what extent are comprehensive centers involved in cancer control and prevention research in their region? (7) How should a "partnership" be established between centers and the NCI to plan future directions of cancer research?

The question regarding the accomplishment of centers is the question that is most frequently addressed. Precise data are lacking to quantify these accomplishments, since in the matrix-type center, it is difficult to select out the relative contributions of the center from those of the parent institution. However, it is the opinion of many that cancer centers have made very significant contributions in basic and clinical cancer research, patient care, training, and education. Additionally, centers have recruited a significant number of new investigators into cancer research. Approximately 50% of all funded investigator-initiated research grants are held by scientists who are members of a cancer center (R. Morrison, oral communication, March 1988). Centers have attracted private and institutional funds that, combined with available federal funds, have made possible the addition of large amounts of new research space and equipment and have subsidized a significant amount of research activity. It is the opinion of many working in the cancer field that cancer centers have become one of the most effective, but not the only, location where new findings arising from basic laboratory research can be most rapidly and efficiently evaluated. Centers have emphasized compassionate care for patients by developing a variety of patient support programs.

An example of the matrix-type university cancer center is the Comprehensive Cancer Center at Duke University, Durham, NC, established in 1972. Fifty-five members of the medical school faculty were founding members. An organizational structure was created, with the center director reporting directly to the University Chancellor for Health Affairs; all center members originally held primary appointments in a medical school department. The growth of the center has been dramatic. There are now 200 members of the center, research space has tripled in amount, and funds for research have increased tenfold. There are, at present, 225 active clinical research protocols and approximately 1500 patients annually accessed into these studies. There were 2700 scientific publications by members of the center during the past six years. A recent reorganization of the center will permit the recruitment of 14 to 16 tenure tract investigators, with primary appointment in the cancer center and secondary appointment in a medical school department. The center is now being referred to as a "matrix-plus" type.

An enterprise as large as the NCI Cancer Centers Program has, as one might expect, encountered several problems during its evolution. Initially, there was some reluctance on the part of some faculty members and administrators of university medical schools to embrace the idea of superimposing a categorical center on an organization that operates with a discipline-oriented departmental structure. There has been a lack of full participation by surgeons in research programs in some institutions with cancer centers. Reduced federal funding of cancer support grants for centers at times has caused retrenchment of research activities in some centers. Additional problems that affect research performance in centers are (1) the issue of animals in research, (2) Federal Drug Administration constraints on new cancer drug approval, (3) inadequate ways to finance hospital costs of inpatient cancer research, (4) financing the high cost of new approved drugs, and (5) constraints arising from legal and ethical issues related to research.

A small number of "cancer centers" have been established with private funding without or with minimal peer-reviewed NCI-supported research, and without an NCI-funded core support grant. A private for-profit corporation is in the process of establishing "comprehensive cancer centers" in several locations in the country.

Results of Surgical Excision of One to 13 Hepatic Metastases in 98 Consecutive Patients

John P. Minton, MD, PhD; Walter B. Hamilton; Armando Sardi, MD; Carol Nieroda, MD; Brenda Sickle-Santanello, MD; Patrick J. O'Dwyer, MD

• Metastatic carcinoma to the liver is generally considered to be associated with a poor prognosis, with five-year survival of only 20% to 30% after resection of solitary lesions. Ninety-eight consecutive patients underwent the surgical removal of one to 13 metastatic lesions from the liver. A rising carcinoembryonic antigen level was considered an indication for reexploration. All gross tumor was removed in every patient; 66 had more than one metastasis. Survival was unexpectedly high: 91 of 98 were alive at 12 months, 50 (70%) of 71 at 13 to 24 months, 23 (66%) of 36 at 25 to 36 months, 14 (74%) of 19 at 37 to 48 months, six (60%) of ten at 49 to 60 months, four (80%) of five at 61 to 72 months, and two (50%) of four 73 to 84 months after resection of multiple liver metastases. The procedure appears to be a safe and, in some patients, beneficial surgical technique for the removal of multiple hepatic metastases.

(*Arch Surg* 1989;124:46-48)

Hepatic metastases from gastrointestinal tract cancer are fatal, and multiple metastases to the liver have been considered not a surgically treatable condition. The median survival of untreated patients with hepatic metastases ranges from 3.1 to nine months.[1] Successful early detection of metastases to the liver is difficult because the anatomic location of the liver makes clinical discovery of metastases less than 3 cm in diameter difficult.[2] Resection of solitary hepatic metastasis has become the treatment of choice, with five-year survival ranging from 20% to 30%,[3-6] but multiple hepatic metastases are often ignored from a surgical standpoint. Biopsies may not even be performed in patients with more than one metastatic lesion. Patients with unresectable lesions are treated with intra-arterial or portal vein chemotherapy when appropriate.

During the past seven years, 98 patients with one or more hepatic metastases (one to 13) have been operated on and all detectable metastatic tumor was removed, with acceptably low blood loss, no mortality, and low morbidity. We present the results of these operations as well as a description of our technique, which, for lack of a better description, we call the "Swiss cheese" procedure because the liver frequently looks like a Swiss cheese when the operation is completed.

PATIENTS AND METHODS

Patients

Between 1980 and 1987, 98 patients were evaluated for second-look operations because of a rising carcinoembryonic antigen (CEA) level or other objective evidence of metastasis to the liver. Primary cancer had occurred in the colon in 72, in the rectum in 12, in the breast in six, in the ovary and pancreas in two each, in the kidney and esophagus in one each, and as melanoma in two.

Serial CEA levels were measured every two months for two years and then every three months for three years after primary colon and rectal cancer resection.[7] Based on a persistent rise in the CEA level, 98 patients were readmitted to the hospital. Liver and spleen scans, abdominal echograms, and computed tomographic (CT) scans were obtained, and the presence of an elevated CEA level was confirmed. A rise in the CEA level above the baseline established after resection has proved to be a reliable indicator of recurrence.

Computed tomographic scans of the abdomen and liver were performed, along with gastrointestinal tract barium contrast roentgenographic examinations. Of the 98 patients, 19 (19%) were reoperated on with a rising CEA level as the only indication; 66 had a positive CT scan of the liver. When multiple metastases were demonstrated outside the abdominal cavity, in lungs or bone, operation was not undertaken.

Surgical Approach

Through a midline xyphoid-to-pubis incision with xyphoidectomy, the abdomen was explored and adhesions were taken down. When tumor was found elsewhere in the abdomen, it was resected (59 of 98 patients). The right lobe of the liver was dislocated from its attachments to the diaphragm and retroperitoneum by means of the elongated electrocautery tip set on 55 coagulation only. The triangular ligament of the left lobe was detached in the same fashion. The falciform ligament was detached from the diaphragm. Liver lesions were identified by bimanual examination of each lobe. With an assistant holding the dislocated liver lobe in the midline of the abdomen, the electrocautery was placed on 110 coagulation and dissection with a 1-cm margin of normal liver was carried out around each lesion. The flat cautery blade worked best, and a laser unit vacuum removed the smoke. Sodium oxychloroscene (Chlorpactin) (7 g/1000 mL H_2O) irrigation to the dissection site was used only when active bleeding occurred. Oxidized regenerated cellulose (Surgicel) was packed and held on persistent bleeding sites. Small metal clips were wedged onto vessels and bile ducts before transection when possible. A 2- to 3-mm brushlike stroke with the flat cautery tip away from the tumor provided the technical motion best for hemostasis during the dissection. One or more No. 1 Black-Braided nylon (Surgilon) sutures were placed through each lesion for the assistant to retract to expose the undersurface of the tumor during dissection. Occasionally, bending the distal one fourth of the electrocautery

tip 45° facilitated the dissection. Large vessels were usually found deep, and counterpressure from the assistant's fingers on the back of the liver decreased bleeding. The Pringle maneuver was seldom used, and usually it was not even necessary to isolate the portal triad to secure vascular control.

When all detectable lesions were removed and the defects were dry, Oxidized regenerated cellulose pressure packets were removed. If the surgeon was concerned about the completeness of the tumor resection, Oxidized regenerated cellulose soaked in fluorouracil was left in the cavity. Drains were usually not used. However, when multiple lesions were removed, a closed fluted No. 19 drain was inserted. If no bile leak was seen by the third day, the drain was removed.

When four or more lesions were removed from the liver, hepatic artery Broviac and a portal vein Hickman catheters were placed in the gastroepiploic artery and vein for the delivery of chemotherapy. To check catheter placement, 3 mL of fluorescein dye was injected only into the arterial catheter to ensure that the dye evenly fluoresced in the right and left lobes of the liver, not the intestines. If the dye appeared in the intestines and the catheter position could not be improved, the hepatic artery was identified and the gastroduodenal branch isolated and catheterized with the catheter tip placed in the common hepatic artery for infusion to the left and right lobes of the liver. The catheters were inserted through the skin in the right upper quadrant of the abdomen. Before discharge, the patient was taught how to care for the catheter and self-administer chemotherapy consisting of 2 mL of fluorouracil in each catheter at 6 PM five of seven days per week, followed by heparin.

RESULTS

Of the 98 patients operated on, 59 had resection of metastases outside the liver. A total of 191 liver lesions were resected; 108 were in the right lobe and 83 in the left lobe. Metastases ranged from 0.5 to 20 cm in diameter, with the most frequent lesion size being 2.0 cm in diameter (44 metastases). Thirty-two patients had solitary hepatic metastases; 66 had more than one. Table 1 shows the number of lesions resected per person; Table 2 shows the size of the lesions resected and the lobe from which they were removed. The average intraoperative blood loss was 434 mL (range, minimal to 1200 mL). No blood transfusions were given during the last 50 operations.

The average hospital stay was ten days (range, five to 18 days), with 58% discharged on the tenth day. There were no deaths in the operating room or within 30 days postoperatively. Three patients had bile fistulas; two stopped draining in less than one month and one drained for three months. One patient suffered a postoperative myocardial infarct.

Ninety (91%) of the 98 patients were alive at the end of one year, 50 (70%) of 71 at 13 to 24 months, 23 (66%) of 35 at 25 to 36 months, 14 (74%) of 19 at 37 to 48 months, six (60%) of ten at 49 to 60 months, four (80%) of five at 61 to 72 months, and two (50%) of four 73 to 84 months after operation.

COMMENT

Acceptance of the concept that more than one metastatic liver lesion can be removed will obviously take time and a record of successful surgical experience. Our series of patients reflects our experience with the resection of multiple metastatic lesions, primarily from colon cancer. Excision of more than one lesion began innocently, when several small (1- to 3-cm) lesions were discovered during a CEA-directed second-look operation.[8] These were superficial and easily removed with the electrocautery, associated with no excessive blood loss, no residual tumor, no postoperative morbidity or mortality, and a CEA level that was normal one month after operation.

The insertion of catheters for postoperative chemotherapy was suggested by Taylor and West's[9] report that after primary colon cancer resection, the injection of fluorouracil into the portal vein decreased metastatic cancer to the liver. The insertion of both a hepatic artery and portal vein catheter was thought to be better. If either catheter failed, a second catheter was available. Undetectable residual metastases would receive chemotherapy from both arterial and venous routes. Insertion of both catheters took little extra time, and the arterial perfusion pattern could be confirmed by injection of 3 mL of fluorescein dye. When there were fewer than four metastases, catheters were not placed unless the metastatic lesions were of different size, suggesting persistent tumor shedding rather than a single embolic event.

Technically, most of these lesions are easily removed without risk of excessive blood loss. However, there are three areas that deserve comment because of potential bleeding. In the right lobe, the posterior lateral and superior area, and anteriorly at the vena cava in the area of the junction of the right, left, and central hepatic veins, care must be taken to avoid bleeding, since exposure through a midline incision does not permit easy access to accomplish hemostasis in patients who are obese or those who have a high diaphragm.

Preoperative tumor detection by CT scan, magnetic

resonance image, and ultrasound is, at best, barely adequate. When more than one lesion exists, or when lesions are 2 cm in diameter or smaller, they are seldom identified. The best detector of metastases is a careful intraoperative bimanual examination. The intraoperative ultrasound is an interesting instrument that shows the location of vessels in relation to the tumor, but it has not demonstrated a metastatic lesion that could not be felt.

The shapes of the metastatic lesions resected were spherical, ovoid, and, occasionally, dumbell shaped. A true three-dimensional orientation is important in dealing with each lesion. Surface lesions tended to appear spherical on bimanual examination but only occasionally were as deep in the liver as they were wide.

When smaller lesions are removed, each margin must be checked at least by gross examination. When margins were questionable, the defects remaining after tumor removal were reexcised or laser vaporized and packed with oxidized regenerated cellulose soaked in a 6% aqueous phenol (Aqua Phenol) solution or fluorouracil in an attempt to reduce the survival of residual tumor cells. No untoward effects were observed in any patient from such packing or chemotherapy.

The self-administration of chemotherapy significantly reduces the overall cost of this management technique. Evening (6 PM) administration was selected because of reported tumor susceptibility to chemotherapy at that time and host resistance.[10] The lack of any significant toxic reactions and the unexpectedly long survival suggest that all gross tumor resection coupled with prolonged chemotherapy given directly into the hepatic circulation for extended periods of time is safe and effective in patients with hepatic metastases from colorectal tumors.

This study was supported by the American Cancer Society, National Chapter, Phi Beta Psi Sorority, and the H. L. Block Liver Metastasis Research Fund, and the Grand Chapter of the Ohio Eastern Star.

Discussion

Q What are your criteria for and against embarking on this exercise?

A If there is diffuse disease in the lungs or obviously diffuse disease in the liver, then those patients are not candidates for exploration. If you have solitary or multiple solitary lesions or individually definable lesions in the liver, then they, I think, become candidates for this type of procedure. The surgeon at the operating table has to make a decision on what can be done safely and what cannot be done safely. During the operation a little pressure from the posterior aspect of the liver by the assistant and electrocautery on the highest coagulation setting really helps keep the blood loss to a minimum, and one can do these metastases safely and most of the time remove all the disease.

Q So there is no maximum above which you would say that you would not do it. Is it more a question of technical ability to get to where they are and do them?

A I have two patients with eight metastases removed surviving right now. I think the more disease you have, the less likely you are going to be able to keep these patients under control.

Q I have a question specifically about the chemotherapy regimen that you used. How long do patients continue to receive chemotherapy? I think you said you administered chemotherapy to all patients who had four or more metastases. What number of your long-term survivors are in fact in that group and what number are in the four or fewer metastases group?

A You have to take into consideration that the five-, six-, and seven-year survivors are people who had either one or two lesions. Those people did not get the lines, and I became a little more aggressive as I became more comfortable with the concept, and that is when we get into our multiple lesions. Patients with multiple lesions receive chemotherapy until their catheter is either thrombosed or broken and they refuse to have a new catheter put back in or until five years.

Q What dosage schedule are you using?

A It is very simple. I simply use 2 mL in each catheter at 6 PM until they experience diarrhea or toxic reaction, and then we just stop treatment until they recover and then reduce the dose and start them back on their home self-administration.

Q Both we and Hughes in the big national study found that margins less than 1 cm were highly correlated with poor outcome. I wondered what kind of margins you strove for. In looking at your data, it looked to me as if the median number of nodules was less than two for the whole series. So I guess the question I am actually asking is, how many had the larger numbers? In almost all the reports, the survival of patients with more than three or four separate nodules has been very poor, although not zero. I wonder about the other prognostic features too. For instance, most of the reports in the literature do not indicate a correlation between size of the nodule and the outcome, as if this were a biologic phenomenon of solitary lesions rather than a temporal phenomenon of catching them early. I wonder what your thoughts would be about that.

A To answer the question of the number of individuals with solitary lesions, I will go through those numbers: 32 had one lesion, 34 had two lesions, five had three lesions, three had four lesions, three had five lesions, two had six lesions, one had seven lesions, one had eight lesions, one had nine lesions, and one had 13 lesions.

We are still looking at flow cytometry. I do not have a good answer for that. The other factor probably related to poor survival is whether they do or do not make CEA. The patients who did not warn us early on, of course, had larger and frequently more extensive disease. The patients who had small lesions and high CEA values probably had a better clinical survival. I do not have all those data completed yet, but those are important factors, and I do agree that the biologic nature of the tumor is the answer in these people.

We always try for margins of 1 cm. I did not get these margins all the time and when margins were close or positive. What I did was take some oxidized regenerated cellulose and soak it in 6% aqueous phenol and pack it in the hole left by tumor removal. Nothing can survive local phenol. It is the same phenol that you use to inject around nerves to decrease the pain in pancreatic carcinoma. Patients tolerate it well.

Q Where did the recurrences develop in those who experienced recurrence?

A They were almost equal in the lung, liver, and abdomen. Those who died with recurrent tumors were just about equal, but I was impressed with the years of extended survival in patients with "Swiss cheese" resections that later failed.

Experimental Liver Metastasis

Implications of Clonal Proclivity and Organ Specificity

T. S. Ravikumar, MD; John D'Emilia, MD; Celia Cocchiaro; Barbara Wolf, MD; Vincent King; Glenn Steele, Jr, MD, PhD

• "Spontaneous" lung metastases develop in over 50% of the animals bearing subcutaneous isografts of WB-2054, a rat colon carcinoma. A metastatic variant has been developed by "Fidler" type in vivo selection, yielding 100% lung metastasis. In a five-week assay to test the organ specificity of this lung metastatic variant, however, "experimental" liver and lung metastases could be induced in 100% and 60% of animals on portal venous and intravenous injections, respectively. The results demonstrate selection of a metastatic variant from heterogeneous primary tumor, and suggest at least two interacting mechanisms: (1) mechanical (the anatomy of the blood-borne metastatic pathways) and (2) biologic (factors intrinsic to primary tumor subpopulations that can be selected for metastatic proclivity). In addition, liver metastases were successfully established from colon tumors induced by cecal wall injection of tumor cells. Such a spontaneous liver metastasis model will be useful to study the specific mechanisms involved during metastasis of colon cancer to the liver.
(*Arch Surg* 1989;124:49-54)

Death from liver metastases remains a significant problem in cancer-related mortality. Colorectal carcinoma metastasizes to the liver in up to 70% of patients who develop advanced disease.[1] Other gastrointestinal tumors and extra-abdominal tumors of diverse origin metastasize to the liver frequently.[2] No effective therapy is available for nonresectable hepatic metastases.[3]

Experimental studies for understanding the mechanisms of organ-specific metastases are germane to designing proper therapeutic strategies. Such studies are limited by the lack of suitable animal models for liver metastasis.[4] A spectrum of chemically induced rodent and murine tumors and xenografts of human colon carcinoma in nude mice or rats have been described to study human colon cancer metastasis, not all of them reflecting accurately the complex steps involved in the metastatic pathway.[4-9] Few of these models display reproducible metastatic properties that are analogous to the clinical setting, and most of these systems involve induction of metastases by subcutaneous, tail vein, or intrasplenic injection. A shortcoming of the nude mice models to study the mechanisms of metastasis is that spontaneous metastases do not occur ordinarily in nude mice or occur only very rarely.[10,11] Though the in vivo studies using human tumor xenografts in immunosuppressed nude mice may be acceptable for many experimental purposes, tumor models utilizing syngeneic animal systems offer advantages of being able to study the metastatic "cascade" in immunocompetent hosts.

To this end, we have attempted to develop a model to study metastasis in a chemically induced syngeneic rat colon cancer, which has previously been shown to bear reasonable analogy to human colon carcinoma.[12,13] We have successfully established liver metastases from colon tumors induced by cecal wall injection of tumor cells, thereby providing a model that follows all the steps of the complex metastatic pathway.

Though it is generally accepted and proved in several animal tumor systems that metastasis is a nonrandom multistep process with selection of cell variants with predetermined target organ specificity,[14,15] autopsy data of patients dying of colon cancer reveal a cascade phenomenon of metastasis, conforming to a circulatory "watershed" principle.[16,17] These data are persuasive as to the interplay between the biologic characteristics of tumor cell subpopulations, host organ microenvironmental influences, and the circulation dynamics of tumor cell dissemination in the development of tumor metastasis. In this study, we have also tested the implications of organ specificity vs circulation dynamics by utilizing a metastatic variant of the rat colon cancer cell line and inducing experimental lung and liver metastases.

MATERIALS AND METHODS

Animals

Wistar-Furth–Brown Norwegian F_1 hybrid rats (WF × BN F_1) were bred in our institutional animal facility by mating female Wistar-Furth rats and male Brown Norwegian rats (Harlan Sprague-Dawley). The F_1 hybrid rats were used at 8 to 9 weeks of age. The animals were allowed free access to food and water.

Accepted for publication Sept 2, 1988.

Read before the Annual Meeting of the Society of Surgical Oncology, New Orleans, May 23, 1988.
Reprint requests to 110 Francis St, Suite 3A, Boston, MA 02215 (Dr Ravikumar).

Tumors

The WB-2054 tumor is a poorly differentiated mucin-producing colon adenocarcinoma, induced by 1,2-dimethylhydrazine in a WF × BN F_1 rat. This tumor is syngeneic to the F_1 hybrid rats. The tumor line is maintained both by serial in vivo passage in the subcutis and by in vitro cell culture. A metastatic variant of the WB-2054 cell line was established as described below.

Single-cell suspensions were prepared from solid tumor isografts by mechanically disaggregating small tumor pieces, suspended in RPMI 1640 medium with 1000 IU/mL of penicillin and 100 mg/mL of streptomycin. The cells were washed three times in the same medium and resuspended at appropriate concentration in phosphate-buffered saline.

Induction of Spontaneous Metastases

The term *spontaneous* metastasis is used to describe the ability of cell subpopulations from within the primary tumor isografts to progress and form metastatic foci to regional lymphatics and distant organs. Eight- to 9-week-old male WF × BN F_1 hybrid rats were injected subcutaneously in the thigh with 1×10^6 cells. Tumors thus induced were resected (under ether inhalation anesthesia) at four weeks and the rats were followed up for an additional eight weeks. At this time, all rats were killed by ether inhalation and autopsied for evaluation of lungs and livers for metastasis.

Isolation of Metastasis Variant

A cell line with enhanced metastatic ability was selected by an in vivo method similar to the description by Fidler.[18] Cells derived from spontaneous lung metastases in rats bearing primary tumor isografts were reimplanted subcutaneously, and the procedure was repeated serially in an attempt to isolate cells with enhanced metastatic ability.

Growth Kinetics of Primary Tumor and Metastatic Variant

Single-cell suspensions (1×10^6 live cells) of WB-2054 primary tumor and its metastatic variant were injected subcutaneously into the thigh of male WF × BN F_1 hybrid rats. Tumor isograft growth was measured twice weekly with Vernier calipers and the tumor volume determined by the method of Attia and Weiss.[19]

Metastatic Progression of Tumors

Two groups of rats were injected subcutaneously with 1×10^6 cells of either the WB-2054 primary tumor or its metastatic variant. Groups of rats were serially killed at weekly intervals, at three to eight weeks following tumor cell inoculation. Lungs and liver were dissected and examined for gross and microscopic evidence of metastasis.

Induction of Experimental Metastases

The term *experimental* metastasis signifies metastases developing after intravascular injection of neoplastic cells.[20] Single-cell suspensions (1×10^6 cells) of either primary tumor or the metastatic variant were injected intravascularly using a 26-gauge needle. For intravenous injection, the rats were subjected to light ether inhalation anesthesia, and the jugular vein was exposed in the neck by a 5-mm incision. Following the injection of tumor cells, gentle pressure was applied over the venipuncture site for about a minute and the skin closed with a metallic clip. For portal vein injections, a midline abdominal incision was made with the animal under ether anesthesia, the duodenal loop was exposed, and the tumor cells were injected into the portal vein. Sterile absorbant sponge was placed under gentle pressure over the injection site as the needle was withdrawn to prevent bleeding and peritoneal spillage of tumor cells. The abdominal wall was approximated with running 3-0 chromic catgut sutures and the skin approximated with metallic clips. Five weeks following tumor cell injections, the rats were killed for harvesting liver and lungs. Gross inspection and microscopic examination of 10% formaldehyde–fixed tissue was carried out to detect metastatic deposits.

Table 1.—Incidence of Lung Metastases Eight Weeks Following Resection of WB-2054-Primary Isografts

Experiment	No. of Rats: Isograft	No. of Rats: Lung Metastases	Percentage of Lung Metastases
1	10	5	50
2	6	4	67
3	12	7	58
Total	28	16	57

Induction of Spontaneous Liver Metastases by Cecal Injection of Tumor Cells

Male WF × BN F_1 rats were anesthetized by ether inhalation, and the cecum was exposed via a midline abdominal incision. Five million viable tumor cells (in 0.05 mL of phosphate-buffered saline) of WB-2054 or its metastatic variant were injected into the cecal wall from the serosal side using a sterile tuberculin syringe and a 27-gauge needle. The serosal surface of the injection site was dabbed with 95% alcohol swab to kill any tumor cells on the peritoneal surface. The abdominal wall was closed as described above. The rats were subjected to laparotomy every four weeks and examined for the presence of cecal tumors and liver, lymph node, or peritoneal metastases. In rats with established cecal tumors and metastases, the organs were removed and processed for histologic analysis.

Statistical Analysis

The χ^2 test with Yates' correction was used to assess the statistical significance of the incidence of parenchymal metastases.

RESULTS

Spontaneous Metastases From WB-2054 Primary Tumor Isografts

Four weeks after subcutaneous injection of 1×10^6 WB-2054 colon tumor cells into the thigh, all rats developed tumors measuring approximately 2 to 3 cm in diameter, when the tumors were resected. At eight weeks following resection of these primary tumors from the thigh, the lungs and the liver were examined grossly and microscopically. None of the rats developed liver metastasis. The incidence of lung metastases observed in three sequential experiments is summarized in Table 1. The mean incidence of lung metastases was 57% (range, 50% to 67%). We also found that at this period of eight weeks, the metastases in all animals became grossly visible, such that the lungs grossly negative for metastases were also negative on light microscopy using 10% formaldehyde–fixed tissues stained by hematoxylin-eosin.

Isolation of a Metastatic Variant

A Fidler-type selection experiment was carried out to yield a metastatic variant of the WB-2054 tumor. The third selection tumor was chosen as the metastatic variant, as it induced lung metastases in all the rats, the size of lung metastases being significantly larger than those produced by the primary tumor line. The primary tumor line will hereafter be referred to as WB-2054-P and the lung metastatic variant WB-2054-M. The histologic nature of WB-2054-M was poorly differentiated mucin-producing adenocarcinoma, identical to that of WB-2054-P.

Growth Kinetics of WB-2054-P and WB-2054-M

To ensure that the metastatic proclivity of WB-2054-M was not simply due to rapidity of proliferation, we compared the growth curves of WB-2054-P and WB-2054-M isografts induced by subcutaneous inoculation of 1×10^6 cells in two groups of rats. Figure 1 is a semilog plot of the tumor

Fig 1.—Semilog plot of comparative growth kinetics of WB-2054-P and WB-2054-M isografts (n = 3, each group).

volume of exponentially growing tumors. There is no significant difference in the growth kinetics between the tumor lines. After six weeks, the tumors became necrotic, with breakdown of skin, and the volume measurements were unreliable.

Time to Spontaneous Metastasis Development

Serial killing of rats at weekly intervals to examine for lung metastases development was carried out to evaluate the rate of metastatic progression. Both WB-2054-P and WB-2054-M metastasized to lungs after a latent period five weeks following primary tumor resection.

Experimental Metastases to Liver and Lung

Groups of five rats were randomized to receive intravenous or portal venous injection of 1×10^6 cells of either WB-2054-P or WB-2054-M tumor. Five weeks after the tumor cell injection, the rats were killed and all intra-abdominal and thoracic viscera were examined for metastases. Table 2 summarizes the aggregate of two experiments. Intravenous injection of WB-2054-P did not produce parenchymal metastases in any of the rats in this five-week assay. When injected via portal vein, however, 50% of rats developed multiple gross liver metastases; none of these

Table 2.—Parenchymal Metastases Five Weeks Following Tumor Cell Injection*

Cells and Route	Metastases	
	Lung	Liver
WB-2054-P		
IV	0/10	0/10
PV	0/10	5/10
WB-2054-M		
IV	6/10†	0/10
PV	0/10	10/10‡

*WB-2054-P and WB-2054-M indicate primary and metastatic variants, respectively; IV, intravenous; and PV, portal venous. Values are numbers of rats.

†$P<.005$, primary vs metastatic variants, χ^2 test.

‡$P<.01$, primary vs metastatic variants, χ^2 test.

Fig 2.—Gross liver metastases in rat five weeks after portal venous injection of 1×10^6 WB-2054-metastasis cells. Note absence of lung metastases.

rats developed lung metastases. Intravenous injection of WB-2054-M resulted in 60% of rats developing pulmonary metastases. Surprisingly, all animals (100%) receiving portal venous inoculation of WB-2054-M cells, which is a lung metastasis variant, developed liver metastases. One such tumor is shown in Fig 2. Equally interesting, intravenous, WB-2054-M injection did not give rise to liver metastasis, nor did portal venous injection result in lung metastasis. These findings suggest that the arrest of tumor cells in the first capillary bed may be an important determinant of the site specificity of metastases.

Light microscopy of all the harvested organs was carried out to confirm the incidence of metastases (Figs 3 and 4).

Induction of Spontaneous Liver Metastases by Cecal Injection

Cecal injection of WB-2054-P (n = 3) and WB-2054-M (n = 3) tumor cells resulted in development of colonic

Fig 3.—Photomicrograph of liver and lung harvested from rat following intravenous injection of WB-2054-metastasis cells. Lung shows metastatic poorly differentiated adenocarcinoma; normal liver (hematoxylin-eosin, left, ×175; right, ×250).

Fig 4.—Photomicrograph of liver and lung harvested from rat receiving portal venous injection of WB-2054-metastasis cells. Metastatic poorly differentiated adenocarcinoma in liver; normal lung (hematoxylin-eosin, left, ×175; right, ×250).

tumors in all rats. At eight weeks, gross liver metastases developed in two of the three rats receiving WB-2054-M cells, but no liver metastases were seen in rats inoculated with WB-2054-P cells (Fig 5). This experiment demonstrates that the variant tumor with metastatic proclivity could establish spontaneous liver metastases by progressing through all the steps of the metastatic pathway, ie, growth in the colon, progression through the basement membrane, invasion into the vascular bed, dissemination to the liver, and colonization and growth in the liver parenchyma.

COMMENT

The data lend support to the hypothesis that nonrandom selection of metastatic subpopulations from heterogeneous primary tumor is an intrinsic biologic event in the multistep metastatic pathway. Pursuant to this selection process, the metastatic variant selected for proclivity to lung targeting metastasized both to liver and lung, depending on the route of injection. Mechanical factors relating to the anatomy of the lymphatic and blood-borne metastatic pathways seem to be important in determining the target organ site

Fig 5.—Induction of cecal tumor by injection of 5×10^6 WB-2054-metastasis cells into cecal wall. Liver shows gross metastases, and lungs are free of tumor.

rather than a "programming" of the selected metastatic clones to target-specific organs. Additionally, experimental and spontaneous organ-specific metastases could be induced in this model, which lends itself to study various factors involved in lung and liver metastases.

The development of an experimental system for organ-specific metastasis has been prompted by a paucity of suitable animal models to address the questions relating to various steps of the metastatic process in a direct fashion. Nude mice models to study the metastatic characteristics of human tumors are increasingly in use recently. Although for most purposes these models are optimal, the low incidence of metastases even with highly aggressive human tumors, the extreme rarity of spontaneous metastases, and the immunodeficient host milieu have provided the rationale to seek an alternative model with analogy to human colon cancer.[4,7,10,11] A syngeneic model may offer advantage to evaluate immunotherapeutic strategies in an immunocompetent host.[5] Furthermore, the dimethylhydrazine-induced colon cancer model has been

extensively characterized in our laboratory and has been demonstrated to bear reasonable analogy to human colorectal cancer in several respects.[12,13] The ability to induce spontaneous liver and lung metastases in this study makes the analogy even closer.

It is generally accepted that metastasis is not a random process; rather, it involves selection of preexistent tumor cells with higher metastatic potential.[14,15,18,21] The establishment of a metastatic variant by Fidler-type selection in our model supports this tenet. Furthermore, this proclivity does not necessarily correlate with the growth properties of tumor per se, which is demonstrable in this and other models.[8] Heterogeneity during tumor progression and metastasis has been demonstrated with reference to expression of various membrane antigens, karyotypic abnormalities, enzyme and hormone production, and changes in cell surface glycoproteins and glycolipids.[11,22-27] Phenotypic differences between WB-2054-P and WB-2054-M will be pursued in subsequent in vitro studies.

Our finding that a lung metastatic tumor line metastasized avidly to the liver is at variance with the concept of organ specificity of metastases. The postulate of evolution of clonal cell populations that target to lung, liver, or other organs is supported by several studies.[14,18,20] Suppression of tumor metastases by specific organs, organ-specific adhesion of tumor cells, and elaboration of specific factors by target organs are some of the additional mechanisms proposed to support this postulate.[6,28-32] Clinical and experimental observations against such an organ-specific theory have also been put forward. A large autopsy study of patients dying of colon cancer revealed a cascade phenomenon of metastases: development of hepatic metastases via portal veins, metastases to lungs from liver, and finally arterial metastases to other sites from lung.[16,17] In contrast, in patients dying of gastrointestinal cancers outside the portal watershed (upper esophagus, lower rectum), the initial site of dissemination was to the lungs, with subsequent arterial dissemination to other sites. Additionally, strong evidence against organ specificity of metastatic clones has been put forward by Gorman et al.[33] Using a VX-2 carcinoma model in rabbits with portacaval shunt construction, they showed that a primary tumor metastasized according to nonorganophilic circulation dynamics. These clinical and experimental observations are in concordance with our data on experimental metastases. It thus seems likely that spontaneous tumors in humans and in animal models are influenced by an interplay between intrinsic properties of tumor cells, microenvironmental influences in the organs in which the cells arrest, and rheologic considerations.[34]

Despite the fact that organ colonization of cells after direct injection into blood vasculature is not necessarily predictive of spontaneous metastatic potential as shown in this study and by others,[35] such tumor models still are useful to study the interaction between tumor cells and host organ environment. The observation that metastatic cells frequently colonize lung and liver suggests that specific interactions occur at these sites. Specific receptors on tumor cell surface (eg, laminin), specific alterations in glycoproteins (eg, sialoglycoproteins), and elaboration of specific enzymes (eg, type IV collagenase) may be some of the contributing mechanisms.[27,31,36,37] Since it has been suggested that inhibition of sialyl transferase can prevent liver metastasis, we are now attempting to test this hypothesis in our model.[38]

Another postulate that will be addressed in this model is the role of fixed tissue macrophage–tumor cell interactions contributing to lung and liver metastases. Kupffer's cell encirclement of tumor cells injected intraportally was correlated with the metastasizing potential of certain tumor lines in vivo.[39] Stimulation of reticuloendothelial cells has been shown to inhibit metastases and the suppression of these fixed macrophages to increase metastases to liver and lung.[40,41] The establishment of spontaneous metastases to both the lung and the liver in the present study lends itself to study the mechanisms involved in organ-specific tumor cell interactions.

We thank Suzanne Jackson for expert manuscript preparation.

Discussion

Q Did you look microscopically at single-cell suspensions between the primary tumor and your third variant to see if there was any gross difference of the cell membrane? Do you plan to do any biochemical studies to see if there is a difference in the composition?

A Yes, we are in the process of looking at the tumor cell heterogeneity between the primary and the metastatic variants, as well as looking at the interaction between the tumor cells and the host organ subpopulation of macrocytes.

Q What would happen if you did your intracecal injections and tried to do your selections for liver first, perhaps using either your portal vein or an intrasplenic approach, and then compared the two different metastatic variants for biologic activity by, say, titration studies?

A The lung metastasis variant was chosen because it was easy to induce subcutaneous tumor isografts in a large number of animals and, from there, big lung metastases. So far, the cecal injection of the primary tumor does not induce liver metastases, mainly because of the slower kinetics by which animals develop large cecal tumors, obstruction, and peritoneal carcinomatosis. We chose a time point—for example, four to six weeks—where the cecal tumors would be able to be resected but with primary closure and the animals followed up for later development of liver metastases. These studies are in progress.

Q With the lung tumor that you injected intraportally and that formed a metastasis in the liver, if you isolated that metastasis and gave it back intravenously, would it go to the lung again or to the liver in the next generation?

A To the lung again, unfortunately.

Q The Cleveland Clinic group made a subcutaneous pouch that seemed to work quite well. Have you tried that? Does it work?

A We have been successful in doing that, but I do not think we need to do that if we can be successful by injecting into the tip of the cecum and resecting it when the tumors are 1 cm.

ARCHIVES OF PATHOLOGY & LABORATORY MEDICINE

Current Concepts and Diagnostic Evaluation of Autoimmune Disease

Robert M. Nakamura, MD, Walter L. Binder, PhD

This article discusses autoimmune reactions and the numerous mechanisms by which an autoimmune response may be initiated, including genetic factors, T-cell bypass mechanisms, and idiotypes. Human autoimmune diseases are classified into three main groups, ie, organ-specific, non–organ specific, and disorders with non–organ-specific autoantibodies with lesions restricted to one or a few organs, that are examined in detail. General laboratory tests and interpretation of results in relation to state or treatment of the particular disease, age and sex of the patient, and the sensitivity of the test system used are reviewed (*Arch Pathol Lab Med* 1988;112:869-877).

Intra-abdominal Recurrence of Colorectal Cancer Detected by Radioimmunoguided Surgery (RIGS System)

Armando Sardi, MD; Mark Workman; Cathy Mojzisik, RN, MS; George Hinkle, RPh; Carol Nieroda, MD; Edward W. Martin, Jr, MD

• Since 1986, 32 patients with metastatic colorectal cancer have undergone second-look radioimmunoguided surgery (RIGS system). The primary tumor was located in the right and transverse colon in 11 patients, left and sigmoid colon in 16, and rectum in five. The carcinoembryonic antigen level was elevated in 30 patients (94%); all patients underwent a computed tomographic scan of the abdomen and pelvis. The overall sensitivity of the computed tomographic scan was 41% (abdomen other than liver, 27%; liver, 58%; and pelvis, 22%). The RIGS system identified recurrent tumor in 81% of the patients. The most common site of metastasis was the liver (41%), independent of the primary location. Local/regional recurrences alone accounted for 40% of all recurrences. In six patients (18%), recurrent tumor was found only with the RIGS system. The RIGS system is more dependable in localizing clinically obscure metastases than other methods, and carcinoembryonic antigen testing remains the most accurate preoperative method to indicate suspected recurrences.

(*Arch Surg* 1989;124:55-59)

Knowledge of the natural history and failure patterns following the initial resection of colorectal cancer is of primary importance to physicians in choosing adjuvant regimens, as well as in carrying out an aggressive approach to recurrent colorectal cancer.

Many authors have demonstrated the benefits of hepatic resection for liver recurrences of colorectal cancer[1-4] and of the second-look approach to extrahepatic recurrences.[5-7] Many reports on the natural history of the disease are based on the results of physical examination and external scanning, which are known to be inaccurate in determining the extent and location of disease. Radioimmunoguided surgery (RIGS system) has been used at The Ohio State University College of Medicine, Columbus, to locate recurrent tumor and has altered the surgical approach in 26% of patients[8] by identifying tumor not clinically detectable. In this report, we identify the sites of recurrence in a group of patients who underwent reoperations for recurrent colorectal cancer with the assistance of the RIGS system.

PATIENTS AND METHODS

From January 1986 to November 1987, 32 patients underwent second-look surgery for recurrent colorectal carcinoma. Patients with suspected recurrent colorectal cancer who were considered possible candidates for radioimmunoguided surgery were seen in The Ohio State University Clinic.

Diagnostic evaluation of the patients included an air contrast barium enema, a computed tomographic (CT) scan of the abdomen and pelvis, a serum carcinoembryonic antigen (CEA) assay, and colonoscopy. A chest x-ray film, bone scan, and CT scan of the chest were done to exclude patients with extra-abdominal metastatic disease. The presence of either pulmonary or bone metastases excluded the patient from the study.

Patients who were accepted for the study received an injection of iodine 125–radiolabeled antibody. Before the injection, they were treated with a supersaturated solution of potassium iodide salt solution (SSKI) to block the uptake of free radiolabeled iodine by the thyroid gland.

Forearm subcutaneous hypersensitivity testing to the unlabeled antibody (0.1 mg in 0.1 mL of sodium chloride) was performed on the day of injection. If the result was positive, the patient was released from the study. If no reaction occurred, the radiolabeled antibody was given by intravenous injection over ten to 15 minutes, and the patient remained under observation for 15 minutes. Operation was scheduled when precordial counts, measured by the gamma-detecting probe (GDP), were less than 20 counts per 2 s. This usually occurred between two to three weeks after injection (range, three to 34 days).

Patients were admitted to the hospital one day before the operation. Routine bowel preparation was done.

Accepted for publication July 8, 1988.

Gamma-detecting probe (Neoprobe).

GDP

The GDP (Neoprobe, Neoprobe Corp, Columbus, Ohio) is an 18-cm-long by 2-cm-diameter stainless steel tube with an angled tip (120°) for better maneuverability (Figure). Collimation can be varied by a movable stainless steel collimator. The tip of the probe contains a highly radiosensitive cadmium telluride crystal that relays through a preamplifier to emit a digital readout and an auditory signal. The intensity and the frequency of the auditory signal are directly proportional to the level of radioactivity detected. A ratio of 2:1 has been considered to be significant because it is the value at which the audible signal in tumor is clearly different from that in normal tissue.

Monoclonal Antibodies

Two monoclonal antibodies (MoAbs), prepared by hybridoma technology, were used.[9]

All antibodies were labeled with iodine 125 using the (Iodo-Gen) method that has been previously described.[8] The characteristics of MoAbs B72.3 and 17-1A have been previously described.[10-12]

SURGICAL PROCEDURE

A midline xiphopubic incision permitted a thorough exploration of the abdominal cavity with complete mobilization of the liver and small bowel, evaluation of periportal, para-aortic, and celiac nodes, and inspection of previous resection sites and the mesentery. The GDP was used to count obvious tumors and scan the abdomen for areas of increased radioactivity. Areas of obvious tumor were resected if possible, and areas with increased probe counts but without obvious tumor were obtained as biopsy specimens and were sent for frozen-section preparation and examination. Probe readings of normal tissue from which the tumor originated were taken to compare tumor-to-tissue counts. Additional counts were routinely obtained from the liver, stomach, kidney, aorta, small bowel, and colon. Each reading was repeated in triplicate.

Ex vivo probe counts were performed on the gross specimens, and routine and probe-directed samples were obtained for evaluation. Formaldehyde-fixed, paraffin-embedded samples were processed for routine hematoxylin-eosin staining.

Following resection of all recurrent tumor, the bed of resection was counted with the GDP. If increased counts were encountered, the suspicious areas were taken as biopsy specimens, frozen sections were obtained, and, if possible, further resection was carried out until normal counts were obtained. All areas of recurrent tumor were documented and correlated with the final histopathologic results.

Local failure was defined as a recurrence within the tumor bed, in adjacent organs by direct extension, or in regional nodal groups. Regional nodal groups included lymph nodes up to the takeoff of the colic vessels or lymph node–bearing areas adjacent to previous areas of resection. Diffuse disease was defined as three or more sites of noncontiguous tumor recurrence.

Table 1.—Stage of Primary According to Location (Astler-Coller Classification)

	Location, No. of Patients			
Stage	R/Transverse Colon	L/Sigmoid Colon	Rectum	Total
B1	0	4	0	4
B2	3	2	1	6
C1	1	1	0	2
C2	7	9	4	20

RESULTS

A total of 32 patients were studied. The mean age of the 18 men and 14 women was 64 years, with a range of 29 to 82 years.

The modified Dukes' classification of primary tumor was B1 in four patients, B2 in six patients, C1 in two patients, and C2 in 20 patients. The distribution according to primary tumor location is presented in Table 1. Patients were divided into three groups according to patterns of blood supply to see if there was a correlation with the pattern of recurrence: group 1, right and transverse colon (11 patients); group 2, left and sigmoid colon (16 patients); and group 3, rectum (five patients).

The mean time to recurrence was 21 months, with a range of two to 69 months: group 1, 24 months (range, five to 69 months); group 2, 20 months (range, two to 59 months); and group 3, 17 months (range, nine to 28 months).

Sites of Recurrence

Sites of recurrence and their relation to the location of primary tumor are presented in Table 2. Of the 11 patients in group 1, four (36%) had metastasis to the liver only. One patient (9%) had diffuse intra-abdominal disease, as well as liver involvement, and one patient each had recurrences in the mesocolon, mesocolon and small bowel, right paracolic gutter, celiac nodes and retroperitoneum, retroperitoneum and small-bowel mesentery. These last six recurrences could be grouped as local/regional recurrences (55%). In the 11 patients in group 1, there were no pelvic recurrences, and five patients (45%) had some form of liver involvement, either alone or in combination with other sites.

Of the 16 patients in group 2, seven (44%) had metastases to the liver only, one (6%) to the liver and pelvis, four (25%) to the pelvis only, and one (6%) to the pelvis and the anastomosis. Three patients (19%) had diffuse intra-abdominal disease, two of whom had liver involvement as well. Of these 16 patients, ten (62.5%) had liver involvement, and eight (50%) had pelvic involvement, while five (31%) had a local/regional recurrence only.

Of the five patients in group 3, two (40%) had only liver metastases, one (20%) had liver and pelvic metastases, and two (40%) had pelvic metastases. In all, three patients had liver involvement, and three had pelvic involvement.

Overall, 13 (41%) of 32 patients had only liver recurrences, six (19%) had pelvic recurrences alone, two (6%) had liver and pelvic recurrences, and four (12%) had diffuse disease. The other seven patients (22%) had some form of local/regional recurrences. When these seven patients are added to the six patients with pelvic recurrences, 40% had some form of local/regional recurrences alone (Table 3).

Table 2.—Recurrence Sites According to Primary Location in Three Patient Groups

	Recurrence Site, No. (%)				
Group*	Liver	Liver and Pelvis	Pelvis	Diffuse	Other
1	4 (36)	0	0	1 (9)	6 (55)
2	7 (44)	1 (6)	4 (25)	3 (19)	1 (6)
3	2 (40)	1 (20)	2 (40)	0	0

*Group 1, R/transverse colon; group 2, L/sigmoid colon; and group 3, rectum.

Table 3.—Local/Regional Recurrences by Location of Primary

	No. (%)	
Group*	Local/Regional Alone	Overall Local/Regional
1	6 (55)	7 (64)
2	5 (31)	13 (81)
3	2 (40)	3 (60)
Total	**13** (40)	**23** (72)

*Primary location: group 1, R/transverse colon; group 2, L/sigmoid colon; and group 3, rectum.

Table 4.—Preoperative CT Scan of Liver, Abdomen, and Pelvis*

	%		
CT Scan	Accuracy	Sensitivity	Specificity
Abdomen†	71	27	100
Liver	71	58	91
Pelvis	75	22	100
Total	73	41	98

*CT indicates computed tomographic; accuracy = (true-positive[TP] + true-negative[TN])/Total No.; sensitivity = TP/(TP + false-negative); and specificity = TN/(TN + false-positive).

†Refers to CT scan in areas of abdomen other than liver.

Evaluation of Diagnostic Tests

CEA Values.—Carcinoembryonic antigen values were elevated preoperatively in 30 patients (94%). False-negative CEA values (<2.5 ng/mL) were seen in two patients with symptoms who had pelvic recurrences. The overall mean CEA value was 58 ng/mL (range, 1.9 to 298 ng/mL).

CT Scan Results.—Twenty-eight patients had a preoperative CT scan (Table 4). We evaluated the ability of the CT scan to identify tumor in the liver, abdomen (other than liver), and pelvis. Three patients with intra-abdominal disease (other than liver) had a true-positive result, 17 had a true-negative result, none had a false-positive result, and eight had a false-negative result. The sensitivity of the CT scan was 27%, specificity was 100%, and accuracy was 71%. In two of the patients in whom results were considered to be true positive, the amount of disease was underestimated by the CT scan.

Evaluation of results in patients with liver metastases showed that ten had a true-positive result, ten had a true-negative result, one had a false-positive result, and seven had a false-negative result. Sensitivity was 59%, specificity was 91%, and accuracy was 71%. In the ten patients with a true-positive result, the amount of tumor was underestimated by the CT scan in three.

Results of the CT scan of the pelvis were a true-positive in two patients, a true-negative in 19, a false-positive in none, and a false-negative in seven. Sensitivity was 22%, specificity was 100%, and accuracy was 75%. Overall, the sensitivity of the CT scan was 41%, specificity was 98%, and accuracy was 73%.

Other preoperative testing included magnetic resonance imaging of the pelvis in three patients with true-positive results and magnetic resonance imaging of the abdomen in one patient with a false-positive result. Liver/spleen scans in seven patients showed one true-positive result, four true-negative results, one false-positive result, and one false-negative result. Three hepatic arteriograms showed one true-negative result and two false-negative results. All studies combined showed an overall sensitivity of 43%, specificity of 96%, and accuracy of 71%.

Radioimmunoguided Surgery (RIGS System) Results

In 26 (81%) of the 32 patients, the RIGS system identified tumor. In six patients (18%), tumor that was not otherwise clinically evident was found only with the RIGS system. These included a celiac node metastasis in one patient, tumor in the pelvis in one, tumor in the right gutter in one, and tumor in the bed of liver resection in three. In two (6%) of these patients, it was the only tumor found. In three patients, further resection was carried out until free margins of resection were obtained. Twenty-four patients received an injection of MoAb B72.3, and in 20 instances (83%), the antibody recognized tumor. Monoclonal antibody 17-1A was injected in eight patients, and tumor was identified in six (75%). The time between the injection of the MoAb and surgery was 16 days (range, three to 34 days).

COMMENT

During the last decade, aggressive treatment of colorectal cancer metastases to the liver has come into vogue. Five-year survival rates range from 25% to 52%.[1-4] The five-year survival for patients who have undergone multiple reoperations for different patterns of intra-abdominal recurrences has ranged from 23% to 60%,[13,14] with a recent report showing a five- and ten-year actuarial survival rate of 46% and 10%, respectively, in patients with two or more recurrences.[15]

Our series excluded patients with extra-abdominal metastases and, as previously reported, we advocate an aggressive reoperative approach for recurrent colorectal cancer confined to the abdomen.[6,14,15] It has been demonstrated that 37% to 63% of all colorectal cancer recurrences will be confined to the abdomen.[16,17] All patients in our study had pathologic confirmation of sites of recurrences through exploratory laparotomy with the use of the RIGS system. Knowledge of the patterns of recurrences is of primary importance.

Analysis of the patterns of failure after primary colorectal resections showed that the most common site of recurrence regardless of the primary location is the liver, with 16 (50%) of 32 patients showing some degree of liver involvement. Thirteen (40%) of these patients had liver metastasis only. In a previous report by Willett et al,[16] colorectal cancer recurred in the liver in 88 (54%) of 163 patients, but only 31 patients (19%) had liver recurrences alone. Sugarbaker et al[17] found that 63% of recurrences were intra-abdominal, with 24% having liver involvement and 6% with only liver metastases. This difference may be due to the fact that only 60% or less of patients with abdominal failures in this series had surgical or autopsy documentation of the recurrence, and our study included

Table 5.—Local Failure Rates Reported by Different Investigators*

Source, y	No.	% Local/Regional Failure Only	% Total Local Failure
Cass et al,[19] 1976	105	60	78
Olson et al,[20] 1980	69	33	52
Russell et al,[21] 1984	186	14	29
Willett et al,[16] 1984	533	6	19
Gunderson et al,[22] 1985	91	22	48
Sugarbaker et al,[17] 1987	68	9	42
Minsky et al,[23] 1988	294	6	9

*The definition and determination of local failures differ markedly among different investigators.

only patients with confirmed intra-abdominal recurrences and no evidence of extra-abdominal disease. As pointed out by August et al,[18] the problem of the cascade phenomenon (metastases from metastases) makes autopsy studies less relevant to the design of treatment protocols. Therefore surgeons who are involved in the second-look approach to recurrent colorectal cancer should seek recurrence in the liver, regardless of the location of the primary tumor.

Local/regional recurrences alone were seen in two (40%) of five patients with primary rectal cancer, in six (55%) of 11 with right and transverse colon primaries, and in five (31%) of 16 with left and sigmoid colon primaries. The overall local/regional recurrence was 40% (Table 3). This higher incidence of local/regional recurrence, compared with that in other series (Table 5), may be due to the fact that our patients were more closely followed up with repeated CEA determinations every six to eight weeks, which does not allow enough time for the cascade phenomenon to manifest itself. Also, our results are based on the total of intra-abdominal recurrences and not on the total number of patients at risk. The definition of local failure also differs significantly between the different series, and all our patients had surgical and pathologic confirmation of the recurrence. Confirmation was not based on physical examination or laboratory test results as in other series.

Overall local failure rates have been shown to increase with the advancing stage of disease.[16] Primary tumor, staged B3, C2, and C3, have reported local failure rates in excess of 20%.[16,17] In our series, 22 patients had C lesions. The high local recurrence rate can be explained by the failure of surgeons to remove all residual microscopic disease at the time of primary operation.

Some surgeons may question the idea that only a very few patients benefit from a radical colon or rectal excision. Those patients whose tumor involves no lymph nodes constitute approximately 50% of all patients with large-bowel cancer.[24] Whether or not a segmental resection would give the same survival rate as does a radical hemicolectomy depends on the extent of lymphatic spread. If lymphatic spread is limited to epicolic and paracolic lymph nodes (one to five nodes involved), segmental resection only should be as adequate as radical hemicolectomy. However, a subset of patients with involvement of intermediate nodes may have a complete resection only if a radical hemicolectomy with extensive resection of the colonic mesentery is performed. Segmental resection would leave this group of patients with a high likelihood of having residual disease. Gabriel et al[25] proposed that the location of involved nodes influences survival. Patients with local nodes positive for disease (Dukes' C1 group) had improved survival compared with those patients with positive nodes at the point of the prominent vascular ligature (his C2 group).

The use of the RIGS system has been demonstrated in previous studies to alter the surgical approach in 26% of patients, by identifying tumor not clinically detectable.[8] The MoAbs presently used localized in 81% of patients.

In our study, additional tumor was identified in six patients (18%) by the RIGS system, allowing us to resect residual tumor not clinically evident. It may be possible that the use of this technique at the time of primary resection would decrease the incidence of recurrences, especially the high local/regional recurrence that has been reported by us, as well as by other investigators (Table 5). Using a meticulous histopathologic technique, Herrera-Ornelas et al[26] demonstrated that 64% of lymph node metastases were in nodes that measured less than 5 mm. This is one of the reasons that clinical examination alone is not adequate to determine the extent of disease and that other adjuvant techniques are needed.

Newer developments in the MoAb technique may create antibodies with higher affinity, making the RIGS system an even more reliable technique.

Carcinoembryonic antigen determination remains the most accurate preoperative method to detect recurrences; the CEA value was elevated preoperatively in 30 (94%) of the patients. The two patients whose CEA values were normal were symptomatic and were found to have pelvic recurrences. It has been previously reported that patients with pelvic recurrences tend to have lower or negative CEA values,[27] but such recurrences are also more accessible to identification by physical examination.

In contrast, the overall sensitivity of the CT scan was only 41%. For liver recurrences, it was slightly higher (58%), but its value to detect recurrences in other areas of the abdomen and pelvis decreases, especially in areas of the small-bowel mesentery.

Sugarbaker et al[17] found that following primary resection for colorectal cancer, the abdominal CT scan performed three times each year yielded little useful information. Although the sensitivity of the abdominal CT scan in the investigation of patients with suspected recurrent disease was 85%, the false-positive rate was high (45%). The two areas that most frequently showed false-positive findings were the liver and pelvis. Based on these results, the CT scan is not an accurate method to detect recurrences, and response to treatment protocols is greatly jeopardized by relying on this technique.

We conclude that the RIGS system is more dependable in localizing clinically obscure metastases than other methods and that CEA testing remains the most accurate method to detect recurrences.

The authors thank Charlie Agnone, Peter Ferrara, MD, and William Farrar, MD, for their research assistance and Susan Stamper and Helene Ayres for their secretarial-editorial assistance.

Discussion

Q This is an interesting study. I wonder if the authors might consider looking at two subgroups of patients specifically. One is a subgroup of patients in whom multiple intra-abdominal metastases are found. Is each one of these metastases surveyed individually with the authors' probe? The second is a subgroup in whom there are multiple sites that the probe indicates are hot spots and pathologic analyses are performed on these sites. If one looks at these multiple sites, do the correlation and the specificity and sensitivity of the authors' assay hold up?

A For the first question, when we find diffuse intra-abdominal metastases, we really do not make an effort to scan the whole abdomen, because we cannot offer anything more surgical to these patients. There have been some patients in whom each tumor may have different counts because of the heterogeneity of tumor cell lines. However, usually if the primary has been picked up, most of the metastases will be picked up. The studies have demonstrated that this is reliable in 94% of the patients when the primary has picked up the antibody.

Q Can the authors use this method with any kind of external camera before the operation?

A One of the problems with the system now is the type of isotope used. Iodine 125, although very good for use with the probe, cannot be used for external scanning because of its low energy level (25 to 35 meV). Iodine 123, although of an appropriate energy level for external scanning, has the problem that the half-life is only 13 hours. Since we have needed to wait approximately two to three weeks (actually we follow the precordial counts to determine the time for surgery, which has varied from three to 36 days, but mostly about 24 days) for the whole (IgG) MoAb to clear from the blood pool background, this half-life is too short. We are presently in the process of examining dual labeling of MoAbs.

Q How often did this method detect tumor that you would not have found with your laparotomy?

A Approximately 16% of the time.

Q Have you had an occasion to try this repeatedly? That is, can you use this method again on a patient or does this sensitize the patient to the protein?

A Actually, multiple times. Approximately 30 patients have received more than one injection. We do a routine skin hypersensitivity test on those patients prior to reinjection. With the first injection we found a 0.3% incidence of positive skin reactivity; in patients who received more than one injection, this rose to 4%. Any patient having a positive skin test did not receive a subsequent injection. One patient who had a negative skin hypersensitivity test did develop an allergic reaction that responded very quickly to diphenhydramine hydrochloride (Benadryl) administration. The other patients were able to receive up to four injections without any problems.

Q Did the CEA level drop postoperatively in those patients and have any of them had a subsequent recurrence that was not recognized at the first reoperation?

A In most of our patients the CEA level has dropped postoperatively when resection has been possible. It is still very early to tell much about subsequent recurrences. I know that there have been at least two patients who have had recurrences, but I can't give you any further details at this time.

A Computerized System for Evaluation of Residents and Residency Experiences

Thomas G. Quattlebaum, MD, John B. Sperry, MD

Editorial Comment.—Have faculty evaluations of most of your residents ever scored their performances less than excellent? Can other systems offer greater objectivity? In this report, Quattlebaum and Sperry discuss a computerized system that has offered feedback from which deficits were uncovered and acted on by their residents. See if this may be useful for your program.—Hugh D. Allen, MD.

DEFINING A NEW STANDA

RD* FOR EMPIRIC THERAPY

For Infection Following
Complicated Abdominal Surgery

BETTER THAN AMINOGLYCOSIDE COMBINATIONS FOR MOST PATIENTS

For These Reasons...

- ☐ Gram-negative coverage of an aminoglycoside plus
- ☐ Gram-positive coverage of cefazolin plus
- ☐ Anaerobic coverage of clindamycin or metronidazole plus
- ☐ Enterococcal coverage of ampicillin plus
- ☐ Tolerability profile characteristic of beta-lactam antibiotics

...PRIMAXIN Is a Better Choice for Empiric Therapy

Coverage of specified agents is based upon the Microbiology Section of the Prescribing Information as published in the 1988 *Physicians' Desk Reference*®

Data available from Merck Sharp & Dohme, West Point, PA 19486.

PRIMAXIN is contraindicated in patients who have shown hypersensitivity to any component of this product. Before initiating therapy with PRIMAXIN, careful inquiry should be made concerning previous hypersensitivity reactions to penicillins, cephalosporins, other beta-lactams, and other allergens. If an allergic reaction to PRIMAXIN occurs, discontinue the drug. Serious hypersensitivity reactions may require epinephrine and other emergency measures.

In vitro activity does not necessarily imply *in vivo* effectiveness.

*when indicated organisms are suspected at indicated sites

INTRAVENOUS

PRIMAXIN®

(Imipenem-Cilastatin Sodium/MSD)

Please see Brief Summary of Prescribing Information on following page.

Copyright © 1988 by Merck & Co., Inc.

DEFINING A NEW STANDARD FOR EMPIRIC THERAPY

INTRAVENOUS

PRIMAXIN®

(Imipenem-Cilastatin Sodium/MSD)

Contraindications: PRIMAXIN is contraindicated in patients who have shown hypersensitivity to any component of this product.

Warnings: SERIOUS AND OCCASIONALLY FATAL HYPERSENSITIVITY (anaphylactic) REACTIONS HAVE BEEN REPORTED IN PATIENTS RECEIVING THERAPY WITH BETA LACTAMS. THESE REACTIONS ARE MORE APT TO OCCUR IN PERSONS WITH A HISTORY OF SENSITIVITY TO MULTIPLE ALLERGENS.

THERE HAVE BEEN REPORTS OF PATIENTS WITH A HISTORY OF PENICILLIN HYPERSENSITIVITY WHO HAVE EXPERIENCED SEVERE HYPERSENSITIVITY REACTIONS WHEN TREATED WITH ANOTHER BETA LACTAM. BEFORE INITIATING THERAPY WITH 'PRIMAXIN,' CAREFUL INQUIRY SHOULD BE MADE CONCERNING PREVIOUS HYPERSENSITIVITY REACTIONS TO PENICILLINS, CEPHALOSPORINS, OTHER BETA LACTAMS, AND OTHER ALLERGENS. IF AN ALLERGIC REACTION TO 'PRIMAXIN' OCCURS, DISCONTINUE THE DRUG. SERIOUS HYPERSENSITIVITY REACTIONS MAY REQUIRE EPINEPHRINE AND OTHER EMERGENCY MEASURES.

Pseudomembranous colitis has been reported with virtually all antibiotics, including PRIMAXIN; therefore it is important to consider its diagnosis in patients who develop diarrhea in association with antibiotic use. This colitis may range in severity from mild to life threatening.

Mild cases of pseudomembranous colitis may respond to drug discontinuance alone. In more severe cases, management may include sigmoidoscopy, appropriate bacteriological studies, fluid, electrolyte, and protein supplementation, and the use of a drug such as oral vancomycin, as indicated. Isolation of the patient may be advisable. Other causes of colitis should also be considered.

Precautions: *General*—CNS adverse experiences such as confusional states, myoclonic activity, and seizures have been reported during treatment with PRIMAXIN, especially when recommended dosages were exceeded. These experiences have occurred most commonly in patients with CNS disorders (e.g., brain lesions or history of seizures) and/or compromised renal function. However, there have been reports of CNS adverse experiences in patients who had no recognized or documented underlying CNS disorder or compromised renal function.

Patients with severe or marked impairment of renal function, whether or not undergoing hemodialysis, had a higher risk of seizure activity when receiving maximum recommended doses than those with no impairment of renal function; therefore, maximum recommended doses should be used only where clearly indicated (see DOSAGE AND ADMINISTRATION).

Patients with creatinine clearances of ≤5 mL/min/1.73 m^2 should not receive PRIMAXIN unless hemodialysis is instituted within 48 hours.

For patients on hemodialysis, PRIMAXIN is recommended only when the benefit outweighs the potential risk of seizures.

Close adherence to the recommended dosage and dosage schedules is urged, especially in patients with known factors that predispose to convulsive activity. Anticonvulsant therapy should be continued in patients with known seizure disorders. If focal tremors, myoclonus, or seizures occur, patients should be evaluated neurologically, placed on anticonvulsant therapy if not already instituted, and the dosage of PRIMAXIN re-examined to determine whether it should be decreased or the antibiotic discontinued.

As with other antibiotics, prolonged use of PRIMAXIN may result in overgrowth of nonsusceptible organisms. Repeated evaluation of the patient's condition is essential. If superinfection occurs during therapy, appropriate measures should be taken. While PRIMAXIN possesses the characteristic low toxicity of the beta-lactam group of antibiotics, periodic assessment of organ system function during prolonged therapy is advisable.

Drug Interactions—Since concomitant administration of PRIMAXIN and probenecid results in only minimal increases in plasma levels of imipenem and plasma half-life, it is not recommended that probenecid be given with PRIMAXIN.

PRIMAXIN should not be mixed with or physically added to other antibiotics. However, PRIMAXIN may be administered concomitantly with other antibiotics, such as aminoglycosides.

Carcinogenesis, Mutagenesis, Impairment of Fertility—Gene toxicity studies were performed in a variety of bacterial and mammalian tests *in vivo* and *in vitro*. The tests were: V79 mammalian cell mutation assay (PRIMAXIN alone and imipenem alone), Ames test (cilastatin sodium alone), unscheduled DNA synthesis assay (PRIMAXIN), and *in vivo* mouse cytogenicity test (PRIMAXIN). None of these tests showed any evidence of genetic damage.

Reproduction tests in male and female rats were performed with PRIMAXIN at dosage levels up to 8 times the usual human dose. Slight decreases in live fetal body weight were restricted to the highest dosage level. No other adverse effects were observed on fertility, reproductive performance, fetal viability, growth, or postnatal development of pups. Similarly, no adverse effects on the fetus or on lactation were observed when PRIMAXIN was administered to rats late in gestation.

Pregnancy—Pregnancy Category C: Teratogenicity studies with cilastatin sodium in rabbits and rats at 10 and 33 times the usual human dose, respectively, showed no evidence of adverse effect on the fetus. No evidence of teratogenicity or adverse effect on postnatal growth or behavior was observed in rats given imipenem at dosage levels up to 30 times the usual human dose. Similarly, no evidence of adverse effect on the fetus was observed in teratology studies in rabbits with imipenem at dosage levels at the usual human dose.

Teratology studies with PRIMAXIN at doses up to 11 times the usual human dose in pregnant mice and rats during the period of major organogenesis revealed no evidence of teratogenicity.

Data from preliminary studies suggest an apparent intolerance to PRIMAXIN (including emesis, inappetence, body weight loss, diarrhea, and death) at doses equivalent to the average human dose in pregnant rabbits and cynomolgus monkeys that is not seen in nonpregnant animals in these or other species. In other studies, PRIMAXIN was well tolerated in equivalent or higher doses (up to 11 times the average human dose) in pregnant rats and mice. Further studies are under way to evaluate these findings.

There are, however, no adequate and well-controlled studies in pregnant women. PRIMAXIN should be used only if the potential benefit justifies the potential risk to the fetus.

Nursing Mothers—It is not known whether this drug is excreted in human milk. Because many drugs are excreted in human milk, caution should be exercised when PRIMAXIN is administered to a nursing woman.

Pediatric Use—Safety and effectiveness in infants and children below 12 years of age have not yet been established.

Adverse Reactions: PRIMAXIN is generally well tolerated. Many of the 1,723 patients treated in clinical trials were severely ill and had multiple background diseases and physiological impairments, making it difficult to determine causal relationship of adverse experiences to therapy with PRIMAXIN.

Local Adverse Reactions—Local adverse clinical reactions that were reported as possibly, probably, or definitely related to therapy with PRIMAXIN were: phlebitis/thrombophlebitis (3.1%), pain at the injection site (0.7%), erythema at the injection site (0.4%), vein induration (0.2%), infused vein infection (0.1%).

Systemic Adverse Reactions—The most frequently reported systemic adverse clinical reactions that were reported as possibly, probably, or definitely related to PRIMAXIN were: nausea (2.0%), diarrhea (1.8%), vomiting (1.5%), rash (0.9%), fever (0.5%), hypotension (0.4%), seizures (0.4%) (see PRECAUTIONS), dizziness (0.3%), pruritus (0.3%), urticaria (0.2%), somnolence (0.2%).

Additional adverse systemic clinical reactions reported as possibly, probably, or definitely drug related occurring in less than 0.2% of the patients or reported since the drug was marketed are listed within each body system in order of decreasing severity: *Gastrointestinal*—pseudomembranous colitis (see WARNINGS), hemorrhagic colitis, gastroenteritis, abdominal pain, glossitis, tongue papillar hypertrophy, heartburn, pharyngeal pain, increased salivation; *CNS*—encephalopathy, tremor, confusion, myoclonus, paresthesia, vertigo, headache, psychic disturbances; *Special Senses*—transient hearing loss in patients with impaired hearing, tinnitus; *Respiratory*—chest discomfort, dyspnea, hyperventilation, thoracic spine pain; *Cardiovascular*—palpitations, tachycardia; *Renal*—oliguria/anuria, polyuria; *Skin*—erythema multiforme, facial edema, flushing, cyanosis, hyperhidrosis, skin texture changes, candidiasis, pruritus vulvae; *Body as a Whole*—polyarthralgia, asthenia/weakness.

Adverse Laboratory Changes—Adverse laboratory changes without regard to drug relationship that were reported during clinical trials or reported since the drug was marketed were: *Hepatic*—increased SGPT, SGOT, alkaline phosphatase, bilirubin, and LDH; *Hemic*—increased eosinophils, positive Coombs test, decreased WBC and neutrophils, including agranulocytosis, increased WBC, increased platelets, decreased platelets, decreased hemoglobin and hematocrit, increased monocytes, abnormal prothrombin time, increased lymphocytes, increased basophils; *Electrolytes*—decreased serum sodium, increased potassium, increased chloride; *Renal*—increased BUN, creatinine; *Urinalysis*—presence of urine protein, urine red blood cells, urine white blood cells, urine casts, urine bilirubin, and urine urobilinogen.

NOTE: Due to the high antimicrobial activity of PRIMAXIN, it is recommended that the maximum total daily dosage not exceed 50 mg/kg/day or 4.0 g/day, whichever is lower.

How Supplied: PRIMAXIN is supplied as a sterile powder mixture in vials, infusion bottles, and single-dose ADD-Vantage*† vials containing imipenem anhydrous and cilastatin sodium as follows: 250 mg imipenem equivalent and 250 mg cilastatin equivalent; 500 mg imipenem equivalent and 500 mg cilastatin equivalent.

Caution: The suspension from vials is not for direct infusion.

Rationale for Aggressive Colonoscopy in Patients With Colorectal Neoplasia

Kumar S. Dasmahapatra, MD, Kevin Lopyan, MD

• The role of colonoscopy in patients with colorectal neoplasia is not well established. The results of colonoscopy, from 1982 through 1987, in 42 patients with cancers who underwent preoperative colonoscopy (group 1), 64 patients with benign polyps (group 2), and 51 patients who were examined only postoperatively (group 3) were reviewed. These results indicated that (1) approximately one third of all findings would have been missed if endoscopy had been performed to only 60 cm; (2) there was a high incidence of synchronous lesions (33.3% in group 1 and 34.4% in group 2); (3) 57% of patients with synchronous cancer and 63.6% of patients with synchronous polyps developed metachronous lesions, compared with 10.7% and 11.9% of patients with a single lesion; (4) there was a higher incidence of metachronous lesions seen in group 3, compared with group 1; and (5) the median interval for noting metachronous lesions in patients who underwent colonoscopy preoperatively was approximately 18 months. These findings endorsed preoperative colonoscopy and aggressive follow-up in patients with colorectal tumors.
(*Arch Surg* 1989;124:63-66)

The last two decades have seen the emergence of colonoscopy as the dominant diagnostic modality in the management of patients with colon cancer. The incidence of synchronous cancers ranges from 1.5% to 10.7%,[1-11] and the incidence of synchronous polyps ranges from 12% to 86%.[1-11] It has also been suggested that preoperative colonoscopy may change the extent of surgery in up to 88% of patients.[1,4-6,12] Many authors have shown that postoperative surveillance colonoscopy helps to detect a significant number of patients with metachronous polyps and cancers.[9,12-15]

While many investigators believe that routine preoperative colonoscopy is a necessity,[1,4-6,8,9] others think that it is not required and that adequate intraoperative palpation and early postoperative colonoscopy will help manage synchronous lesions.[13] Much of the data regarding postoperative colonoscopy is clouded by the absence of preoperative endoscopy findings in many of the patients.[12,14,15] Furthermore, there is no consensus as to the timing and duration of postoperative follow-up.

To answer some of these questions, we have reviewed our experience with over 3500 colonoscopies from 1982 through 1987, and we evaluated the role of preresection and postresection colonoscopy in patients with cancers and benign polyps. We have also compared the results of surveillance endoscopy in patients who underwent preoperative endoscopy with those who did not.

PATIENTS AND METHODS

Eight hundred sixty-seven patients underwent a colonoscopy as the primary diagnostic modality for the evaluation of frank (n = 353) or occult (n = 514) rectal bleeding. The examination was performed up to the cecum in 95% of the patients. Fifty patients were found to have cancers, and 64 patients were found to have benign neoplastic polyps. An additional 43 patients who had not had preoperative colonoscopy, but who were placed on surveillance colonoscopy following curative resection of their cancers, were also included in this study. Patients were divided into the following three groups.

Group 1

This group consisted of 42 patients who were noted to have cancers on their initial colonoscopy and in whom the entire colon was examined. The eight remaining patients with cancers had obstructing cancers and did not have a complete colonoscopy. The mean age of this group was 58.5 years (age range, 42 to 78 years).

Group 2

This group consisted of 64 patients who were noted to have benign polyps on initial examination. Forty-one patients had one to eight (mean, 1.8) adenomatous polyps that ranged from 0.5 to 4.0 cm in diameter, and 23 patients had one to three (mean, 1.1) villous adenomas that ranged from 0.5 to 5.0 cm in diameter. Except for one patient with a large polyp in the rectum, all patients had a colonoscopic polypectomy. Patients with hyperplastic polyps and three patients with carcinoma in situ in the polyps have been excluded from these data and from further analysis. The mean age of this group of patients was 51.5 years (age range, 32 to 79 years).

Group 3

This group consisted of 51 patients, 43 of whom had undergone a colon resection for cancer, without having had a preoperative

colonoscopy. Eight patients with obstructive colon cancers who had not had a complete preoperative colonoscopy are also included in this group. The mean age of these patients was 56.0 years (age range, 43 to 82 years).

Since 1982, following definitive therapy, all patients have been placed on a follow-up program that required a colonoscopy every six months for one year and yearly thereafter. This was in addition to their regular clinic visits where carcinoembryonic antigen level determinations and liver function tests were performed at three-month intervals during their first year and six to 12 months thereafter. Only 12 patients (7.6%) have been unavailable for follow-up, and the remaining patients have had a minimum follow-up of 18 months. Statistical comparisons have been performed using the two-tailed Student's t test and χ^2 analysis where appropriate.

RESULTS

Figure 1 shows the approximate location of the findings in patients with cancer who had their entire colon examined preoperatively. As illustrated, 29% of abnormal findings were beyond the reach of a 60-cm scope. These lesions were at or proximal to the splenic flexure area. Synchronous lesions were noted in 33.3% (11/42) of patients. There was a 7.1% incidence of synchronous carcinomas, and 26.2% (11/42) of patients had synchronous polyps. A follow-up colonoscopy after definitive treatment revealed a 19.1% incidence of metachronous neoplasms. There was a 7.1% incidence (3/42) of a metachronous cancer and a 12% incidence of polyps. Anastomotic recurrences were seen in 7.1% (3/42). The time interval for noting metachronous lesions ranged from six to 54 months, with a median of 18.0 months. The median follow-up period in this group has been 28.0 months (range, 18 to 60 months). Of 14 patients who had synchronous lesions, eight (57%) developed metachronous lesions. In comparison, only three (10.7%) of 28 patients with solitary lesions developed metachronous lesions. This difference was statistically significant ($P<.005$, χ^2 analysis).

Figure 2 shows the approximate location of the polyps in patients in group 2. Thirty-four percent of lesions were beyond 60.0 cm, and synchronous polyps were noted in 34.4% (22/64) of patients. A follow-up colonoscopy following initial definitive treatment revealed metachronous lesions in 29.7% of patients. Twenty-five percent of patients had polyps, and 4.7% (3/64) of patients developed adenocarcinomas of the colon. The median interval for noting metachronous lesions was 19 months, with a range of six to 36 months. The median follow-up in this group was 31 months (range, 18 to 60 months). Of 22 patients who had synchronous lesions, 14 (63.6%) developed metachronous lesions. In comparison, only five (11.9%) of 42 patients with initial solitary polyps developed metachronous lesions. As was seen in group 1, this difference was also statistically significant ($P<.001$, χ^2 analysis).

Figure 3 shows the findings in group 3 patients. Metachronous lesions were noted in 49% (25/51) of patients. An anastomotic recurrence was seen in one patient. The median interval for noting metachronous neoplasms was 8.0 months (range, six to 60 months). In 43 patients, the preoperative barium enema was reviewed. Four patients (9.3%) with synchronous lesions had been identified. One patient was noted to have a synchronous cancer, and three patients had benign polyps. No other synchronous lesion was noted at the time of surgery. A retrospective review of the barium enemas did not reveal any missed lesions.

The findings in the three patient groups are compared in the Table. There was a significantly higher incidence of metachronous lesions in patients who did not undergo preoperative colonoscopy, compared with patients with cancer whose entire colon had been evaluated preoperatively (49% vs 19.1%, $P<.005$). The eight-month median time interval for noting metachronous lesions in group 3, although shorter than the interval in groups 1 and 2 (18 and 19 months, respectively), was not statistically significant. A valid comparison of the incidence of synchronous lesions in patients who were evaluated by colonoscopy (groups 1 and 2) vs barium enemas (group 3) was not possible because not all the x-ray films were available for review, and only nine of 43 patients had air contrast studies.

COMMENT

The data from our study indicate that routine preoperative colonoscopy in patients with cancer helps to detect a large number of synchronous lesions. The incidence of

Fig 1.—Findings in patients with cancer undergoing preoperative colonoscopy (group 1).

Fig 2.—Initial and follow-up findings in patients with polyps (group 2).

synchronous cancers (7.1%) and polyps (26.2% in group 1 and 34.4% in group 2) is in agreement with many previously published series.[1-11] A preoperative colonoscopy not only helps to remove small benign polyps at the time of evaluation, but proponents of this modality believe that the additional colonoscopic findings may change the extent of colon resection in up to 88% of patients.[1,4-6,12] Sollenberger et al[13] recently have challenged this concept, and they believe that adequate intraoperative palpation, together with an early postoperative colonoscopy, avoids the risk and expense of a preoperative colonoscopy. Our data revealed that in patients who had not had a preoperative colonoscopy, no new intraoperative findings were noted in any of the patients in group 3. Heald and Bussey[3] have reported that only 31% of synchronous cancers in their series were palpable. Definite answers to this question, therefore, can only be obtained from well-controlled, prospective, randomized studies. Barium enemas, although widely used preoperatively, have been shown to miss more than a third of the lesions that are detected by colonoscopy.[16] Pagana et al[4] reported that barium enemas had only a 17% reliability rate as a preoperative diagnostic tool. In our study, barium enemas were done on patients in whom a complete colonoscopy was not possible or in patients who underwent diagnostic studies on a different clinical service.

We believe that flexible sigmoidoscopy is inferior to colonoscopy in evaluating patients with rectal bleeding or in the follow-up of patients after resection. Our data, shown in Figs 1 through 3, indicate that approximately a third of the lesions would have been missed if the examination had been limited to only 60 cm or up to the splenic flexure. Data from Greene[17] and Slater et al[18] have shown that there is an apparent shift to the right in the incidence of cancers and polyps, and Dawson et al[19] have shown experimentally that mucosal changes, similar to that which occurs adjacent to cancerous areas, may occur without a pattern or regularity in the entire colon. Therefore, despite the fact that most colon tumors occur in the distal part of the colon, a complete examination is critical when evaluating patients for possible colon tumors.

Fig 3.—Follow-up findings of patients who did not undergo colonoscopy preoperatively (group 3).

Patients with initial synchronous lesions were noted to have a higher incidence of metachronous lesions. This was true for patients with cancers, as well as for those with polyps. Eight (57%) of 14 patients with synchronous cancers and 14 (63.6%) of 22 patients with synchronous polyps developed metachronous lesions, most of which were benign polyps. This is in contrast to only three (10.7%) of 28 metachronous lesions in patients with an initial single cancer and five (11.9%) of 42 metachronous lesions in patients with a single polyp on initial examination. These findings are in agreement with those reported by Carlsson et al[9] and Kronborg et al.[15] These data suggest that patients with synchronous lesions represent a group at greater risk to develop subsequent polyps or cancers than patients with a single lesion.

The timing and duration of postoperative colonoscopy remain unresolved issues. The timing of the initial postoperative endoscopy has varied from three to 38 months.[9,14,15] In our study, excluding the patients who were unavailable for follow-up, all patients had their first postresection or postpolypectomy colonoscopy between six and eight months. Patients who underwent a complete colonoscopy initially (groups 1 and 2) had a median interval of 18 and 19 months, respectively, from the treatment of the primary lesion to the noting of metachronous lesions. These are similar to the figures reported by Carlsson et al,[9] although earlier reports from the same institution had reported much longer time intervals.[14] Patients who were examined preoperatively could therefore be examined at yearly intervals, although those patients who are at risk to develop anastomotic recurrences may undergo a colonoscopy earlier. The significantly higher incidence of noting metachronous lesions in patients who did not undergo a colonoscopy preoperatively (group 3) could simply be explained by the fact that many of these "metachronous" lesions might, in reality, have existed synchronously. The median time interval for noting metachronous lesions in group 3 was shorter than in groups 1 and 2 but not statistically significant. These data support the view that patients who do not undergo endoscopy preoperatively need to be followed up carefully and should undergo early postoperative colonoscopy.

In our study, metachronous lesions have been noted as

Comparative Results in Three Patient Groups

Group	% of Lesions >60 cm	Incidence, %		Recurrence, %	Median Interval (Range) From Primary Lesion to Metachronous Lesion, mo
		Synchronous Lesions	Metachronous Lesions		
1 (n=42)	29	Cancer, 7.1; polyps, 26.2	Cancer, 7.1; polyps, 12	7	18 (6-54)
2 (n=64)	34	34.4	Cancer, 4; polyps, 25	...	19 (6-36)
3 (n=51)	...	...	Cancer, 4; polyps, 45	2	8 (6-60)

late as 60 months after treatment. Although this may justify yearly colonoscopy for at least five years, definite answers regarding how long patients need to be followed up require studies with longer follow-up data. The results from our study certainly endorse the use of preoperative colonoscopy and support aggressive follow-up endoscopy in patients with colorectal neoplasias.

Discussion

Q I have a question about the group of patients who had cancer and underwent a preoperative colonoscopy. In that group, there were metastatic cancers, and I am troubled by that. Were they at the suture line? Were they actually recurrences, or were they missed? If the interval was, in fact, six months between the colonoscopies, I do not understand how they were able to develop metachronous carcinomas within that time.

A The patients who had carcinomas noted at six months had not had a preoperative colonoscopy.

Q In the group of patients who had their colon cleared of all polyps and who then developed another lesion at 18 months, how big was the lesion, and what were the lesions that they developed?

A The mean size of the lesions, which was not mentioned, was 1 cm. Most of the lesions were actually small. It was difficult to measure them accurately, and we got the reports from the pathologist who measured them at the time that they sectioned them. We did point out that we excluded patients with hyperplastic polyps; these were the very tiny polyps that were not included in this analysis.

Q Was any attempt made to look at the number of polyps cleared at the initial session to determine the subsequent chances of developing other neoplastic lesions and to correlate those two?

A We did not look at the number of polyps, but we did look at synchronous vs single lesions; obviously, patients with synchronous lesions are at a much greater risk to develop subsequent lesions.

Q In the patients with carcinoma and synchronous adenomatous polyps, was the type of operation altered because of the synchronous lesions?

A That is a difficult question to answer. I think this should be studied prospectively, but I can tell you that we had eight patients who underwent a subtotal colectomy because of multiple adenomatous polyps in addition to an adenocarcinoma. I cannot tell you whether the extent of resection was increased because of colonoscopy.

Prospective Phase I Trial of Conservative Management of Low Rectal Lesions

David R. McCready, MD; David M. Ota, MD; Tyvin A. Rich, MD; Diva Thielvoldt, RN; J. Milburn Jessup, MD

• The purpose of this study was to assess anal function and to compare the morbidity of local excision and postoperative radiotherapy for rectal adenocarcinoma with the morbidity of abdominoperineal resection. A posterior parasacral approach was used for local excision. All patients had negative margins, and all but one were continent after completion of radiotherapy. Seven patients (29%) had either a wound infection or a fistula in the local excision group. No local failures occurred, although follow-up was only 13 months. Thirteen (50%) of the 26 patients who underwent an abdominoperineal resection developed at least one complication. Combined treatment that spares the rectal sphincters may be preferable in selected patients with low rectal cancer, if long-term disease-free survival is maintained.

(*Arch Surg* 1989;124:67-70)

The standard treatment for adenocarcinoma of the distal part of the rectum is abdominoperineal resection (APR), which was described originally by Miles[1] in 1908. However, local excision of carefully selected, favorable rectal cancers can be as effective as APR in controlling local disease and providing long-term survival without the formation of a permanent colostomy.[2-4] The successful use of local excision alone, using a transanal[5] or posterior approach,[4,6] depends on the selection of this treatment for patients who have exophytic,[7] small (<3 to 4 cm),[4] and well-differentiated cancers[8] that have not penetrated the muscularis propria of the rectum. Approximately 12% to 25% of such patients will have lymph node metastases.[8,9] Yet, clinical assessment of tumor penetration is wrong in about 20% of patients,[10] and if the cancer has invaded through the bowel wall, the chance of lymph node metastases is greater than 50%,[8] and local recurrence rates increase.[8]

Accepted for publication Sept 30, 1988.

Read before the Annual Meeting of the Society of Surgical Oncology, New Orleans, May 25, 1988.

Reprint requests to Department of General Surgery, University of Texas M. D. Anderson Cancer Center, 1515 Holcombe Blvd, Box 106, Houston, TX 77030 (Dr Jessup).

Although APR is usually advised for those patients who, at the time of local excision, are found to have cancers that penetrate through the muscularis propria[4] (T3) or have metastasized to regional lymph nodes,[7] recent evidence suggests that external-beam radiotherapy (XRT), with doses of at least 45 Gy, can control clinically occult local disease after conservative surgery,[11] as well as after APR.[12] Trials using preoperative XRT suggest that, in doses of 45 to 50 Gy, XRT can decrease the number of lymph node metastases found at surgery.[13]

To determine whether the combination of complete local excision of rectal cancers using the posterior parasacral (transsphincteric[14] or transsacral[6]) excision (PSE), followed by XRT, can be safely extended to patients with rectal cancers that penetrate into the muscularis propria (T2), as well through the muscle (T3), a prospective trial was initiated. In this phase I to II protocol, well- or moderately well-differentiated rectal neoplasms, up to 4 cm in diameter and within 0 to 10 cm of the anal verge, were excised with negative margins. Patients with T2 or T3 lesions received postoperative XRT, in addition to PSE, while patients with benign lesions or T1 (confined to the submucosa) cancers just underwent PSE.

The success of this protocol, aimed at preserving anal function, is predicated on the assumption that combined modality treatment (PSE and XRT) will control local disease as well as radical surgery (APR) does T2 and T3 lesions, up to 4 cm in diameter, and that the complications of this treatment program will not exceed those associated with APR. The purpose of this study was to assess the complications of the local excision of rectal cancers using a parasacral approach in combination with selective postoperative XRT and to compare the morbidity of patients who underwent these treatments with the morbidity of a concurrent group of patients with rectal cancer who were treated with APR at this institution.

PATIENTS AND METHODS

All patients had biopsy proved adenocarcinoma of the rectum or villous adenoma before surgery. Those patients who refused standard therapy (APR) or whose tumors were benign provided informed consent and were entered into this prospective protocol that was approved by the institutional review board. No other colonic lesions were present on either colonoscopy or barium

enema. Along with a history and physical examination, preoperative tests included a carcinoembryonic antigen determination, liver function tests (determinations of serum bilirubin, lactate dehydrogenase, aspartate aminotransferase, and alkaline phosphatase levels), serum electrolyte determinations, complete blood cell count with platelets count, and a chest x-ray film. A computed tomographic scan of the pelvis was performed to exclude gross (>2 cm) nodal disease. Patients were excluded if the primary tumor was fixed to the sacrum or pelvis regardless of size, if the tumor was larger than 30% of the bowel wall circumference, or if lymph nodes were palpable or were visualized (>2 cm) on a pelvic computed tomographic scan. The patients' treatment could be converted to APR if there was cancer at the margins of resection or if perirectal lymph node metastases were found.

A PSE was performed at the University of Texas M. D. Anderson Cancer Center, Houston, by one of two approaches: transsphincteric[14] or transsacral.[6] Two to six weeks after surgery, when the wound was healed and bowel function was normal, XRT was begun. Patients who developed rectocutaneous fistulas began XRT after a diverting colostomy was fashioned.

Initial radiotherapy treatment fields were designed to include the entire pelvis plus the immediately draining perirectal lymph nodes and the parasacral incision. This area was given a minimum dose of 45 Gy in five weeks using 1.8 Gy per fraction, five days per week. The radiation portals were then reduced to cover the site of excision with a margin of 3 to 5 cm and treated to a minimum dose of 53 Gy. Photons with an energy of 18 meV or greater were used. Three fields (posterior plus two lateral) were used with strict avoidance of single posterior or direct perineal fields. Patients were treated in the prone position with an open tabletop device to allow mobilization of the small intestine away from the posterior part of the pelvis.

During the same time period, patients with rectal lesions who were treated with APR, but not preoperative radiotherapy, formed the comparison group. Perineal wounds were closed primarily, and the pelvic floor was reperitonealized. Wound infections were defined as drainage of pus that required dressing changes. The diagnoses of neurogenic bladder and impotence were made after consultation with the urology service. All patients whose conditions were diagnosed as neurogenic bladders required self-catheterization. A complication with the colostomy was recorded only if it required an operative revision. The diagnosis of a fistula was made clinically.

Two indexes of anal function were evaluated. The number of bowel movements and the use of diphenoxylate hydrochloride with atropine sulfate (Lomotil) tablets were obtained by a research nurse (D.T.) using a standard questionnaire. Resting involuntary anal sphincter tone and the ability of the anal sphincters to contract voluntarily were assessed by two of the authors (T.A.R. and D.M.O.) at the time of follow-up. A subjective score was given to both the voluntary and involuntary anal tone: 1 (normal), 2 (fair = slight loss), and 3 (poor).

RESULTS

Twenty-four patients have been treated with a PSE of their rectal neoplasms, including 19 patients with T2 or T3 adenocarcinomas who have received postoperative XRT. Demographic and tumor characteristics of this cohort are summarized in Table 1. The median age of this group was 61 years, and there were 13 women and 11 men. Five patients had villous adenomas, one patient had a T1 adenocarcinoma, ten patients had T2 lesions, while eight had cancers that extended through the muscularis propria (T3). Two patients were noted to have perirectal lymph node metastasis at the time of operation. The tumors averaged 3.1 ± 1.6 cm (mean ± SD) in diameter and were situated an average 5.4 ± 2.5 cm from the anal verge. Five cancers were greater than 4 cm, and one cancer was poorly differentiated. All tumors were excised intact with microscopic-free margins.

The characteristics of those patients who underwent an APR during the same time period as those patients who had a PSE at our institution are also summarized in Table 1. This group is presented for comparison and was not randomized or matched to the prospectively evaluated group. While the median age of the patients who underwent an APR and the distance that their lesions were from the anal verge are similar to the group of patients who had PSE and XRT, the other parameters are indicative of more advanced lesions. The patients who were treated with APRs had significantly larger tumors (4.3 ± 1.8 cm) than those patients who were treated with PSEs ($P<.05$, t test), and there were more T3 tumors (18/26, 69%) than in those patients who underwent local excision (8/24, 33%).

No patient died after APR, but 50% (13/26) of the patients who underwent APRs experienced at least one complication (Table 2). There were four (three abdominal and one perineal) wound infections (15%), and four patients (15%) needed a second operation to revise their stomas (three hernia and one prolapse). Most complications were related to the genitourinary system. Four patients (15%) developed neurogenic bladders postoperatively that were treated with self-catheterization, and of 18 men, five (28%) developed impotence.

There were no operative deaths after PSE, but seven patients (29%) had a complication (Table 2). Three patients (12%) with adenocarcinomas developed wound infections, and radiation was delayed one to two weeks until the skin healed. There were four postoperative fistulas (17%); three required temporary diverting colostomies that were taken

down on completion of the radiotherapy, while one patient who had a villous adenoma removed was treated conservatively. All fistulas healed, and these patients have normal anal continence. There were no episodes of urinary retention, sexual dysfunction, or other complications. All patients had transient proctitis during radiotherapy that was manifested by a median of three (range, two to seven) bowel movements per day and was treated symptomatically.

Six months after completion of treatment (surgery and/or radiotherapy), bowel habits, resting anal tone, and the force of voluntary anal sphincter contraction were evaluated in 20 patients by history and physical examination. Nine patients (45%) experienced one bowel movement per day. The median for this group was two (range, one to nine) bowel movements per day. The resting anal sphincter tone was scored as normal in 15 patients, while three patients had a slight loss of tone, and two patients had poor tone. When asked to contract the anal sphincters, all but one patient had a "normal" squeeze pressure (Table 3).

There were two patients who required pads to prevent soiling. Both patients had poor resting anal tone and had postoperative radiotherapy. One of these patients had normal voluntary control of the sphincter but had eight to nine bowel movements per day. The second patient is the only one of the group who has not thoroughly regained control of the external sphincter.

The median follow-up for this cohort was 13 months, and there were no local recurrences. One patient developed metastatic disease to periportal lymph nodes, and another patient died of intractable congestive heart failure 11 months after resection without evidence of disease.

COMMENT

The results of this prospective study demonstrate that the postoperative morbidity after PSE of rectal neoplasms is comparable with the complication rates of a concurrent, nonrandomized group of patients undergoing APR. The addition of postoperative XRT did not preclude an acceptable rate of anal function, and when combined with complete excision of the primary rectal cancer, it may allow more patients to be safely treated without radical excision of the rectum and anus if these early results are maintained.

The complications following PSE reported in this study are similar to other series (Table 4). Rectocutaneous fistulas often present by the eighth postoperative day[14] and, if they are small and of low output, can be managed expectantly. Three patients with invasive cancers developed fistulas and were treated with a temporary colostomy so that radiotherapy could be started without significant delay. One patient with an excision of a villous adenoma was treated without fecal diversion. All fistulas have remained healed, and all patients have had good anal function.

Morbidity after APR in this retrospective analysis is also comparable with findings from previous reports.[21] The diagnosis of impotence and neurogenic bladder was made after urologic consultation, and only stomal complications that necessitated a second operation were included. Direct comparison between the patients who were treated with APR and those patients who received PSEs is limited because patients who were selected for APR generally had more advanced cancers. However, there is no evidence to suggest that PSE and radiotherapy were associated with excessive morbidity.

The majority of patients who have undergone a PSE and postoperative radiotherapy have had excellent anal function. Only two patients required protective pads. It is difficult to compare the anal function in our patients with those patients described in the literature because the number of bowel movements per day and the number of patients using pads is not always documented, but Westbrook et al[22] have reported incontinence in one of 19 patients. Even though diarrhea was experienced by all of the patients during radiotherapy, there was no evidence of anal function impairment after radiotherapy was completed. The subjective method of measuring resting anal sphincter tone and the force of voluntary contraction is admittedly crude and subject to bias, but it allowed us to document improvements during convalescence and suggested that most patients undergoing a PSE and radiotherapy will have full return of anal sphincter function.

Late morbidity in the rectum secondary to the radiation used in this study is expected to be minimal since doses below 60 Gy were used.[11] Small-bowel complications should also be very low since the small bowel is mobile (no laparotomy) and is generally excluded completely from the radiation fields.[13]

The excellent exposure provided by the posterior parasacral approach to the rectum facilitates a complete excision of the lesion for histologic study with microscopic-free margins. It also allows access to the mesorectum so that perirectal lymph nodes can be sampled, which is not feasible using the transanal approach. The choice between the transsphincteric or transsacral method depends on the distance of the lesion from the anal verge; the sphincters are not divided for higher lesions.

Although local excision has traditionally been restricted to small, well-differentiated, superficial, exophytic rectal cancers, this protocol has extended the indications to include neoplasms that have penetrated into the muscularis propria or through this layer. Postoperative radiotherapy was given to control any lymph node metastases and

microscopic residual disease, but this combined modality regimen has little value if local recurrence and survival is not comparable with treatment with APR. The absence of any local failures in this cohort is encouraging, but the median follow-up has been only 13 months, and it is too soon to assess accurately recurrence and survival rates. However, these early results, combined with the relatively low complication rate, suggest that PSE and postoperative radiotherapy constitute a safe treatment regimen and may allow more patients to undergo anorectum-sparing surgery for distal rectal adenocarcinomas.

The authors acknowledge A. Pearse for help with data retrieval and Mae Reinauer for manuscript preparation.

Discussion

Q Do you think that this is a more important question, ie, colostomy vs no colostomy in the T2 and maybe even early T3 lesions, than some of the chemotherapy adjuvant questions that are presently being asked? If you do, do you think that this is ever going to be amenable to a randomized trial of colostomy and no colostomy?

In light of the fact that the Gastro-Intestinal Study Group and the North-Central Cancer Treatment Group have shown that fluorouracil actually is synergistic with effect of radiation therapy, do you think that the best treatment in these T2 and early T3 lesions, which have anywhere from a 30% to 50% chance of microscopic perirectal nodal disease, might be the combination of radiation and fluorouracil rather than radiation alone?

A The first question really relates to the importance of this study, vis-à-vis the stated agenda of the large groups, in terms of asking the questions of chemoradiotherapy added to standard surgery. If one's goal is increasing survival, the goal of the National Cancer Institute, it would seem that a quality of life issue, as to whether or not you want to save the rectum, is not going to be as important politically as a chemoradiotherapy trial that may have survival advantage. I do believe that you will be able to show that local regional control will be as good with a lesser surgical procedure and radiotherapy as standard APR even with postoperative adjuvant radiotherapy.

The second question relates to the role of chemotherapy added to radiotherapy for these lesions. At the M. D. Anderson Cancer Center, we have a second prospective study now under way in which we are looking at those lesions that are greater than 4 cm and that are poorly differentiated. Within that context, the trial includes continuous infusion of fluorouracil with radiotherapy. I am not sure that for the small, well-defined rectal cancers, one necessarily has to add chemotherapy to radiation.

Dr Tyvin Rich's earlier study with radiotherapy alone for incompletely excised rectal cancers demonstrated excellent local control. We, at the M. D. Anderson Cancer Center, have a retrospective series of 16 patients treated with radiotherapy alone for T2 and T3 lesions who have 96% local control after a median follow-up of 18 months. I think that when we do this, we are doing basically a biopsy and then irradiating undisturbed tissue. That may be quite a bit different from doing postoperative therapy in patients who are recovering from the major dissection APR or a low anterior resection.

Q I am very interested to find out if any of your infectious or fistula complications were associated with presacral abscess or extension into retroperitoneal abscesses?

A No. They were not.

Q Do you have any experience with preoperative radiation therapy for these patients?

A Not in this setting. We have actually treated a couple of patients, and the morbidity has been markedly increased because with preoperative radiotherapy, you are performing surgery in an irradiated tissue that has difficulty healing.

Staging Renal Carcinoma

What Is Sufficient?

Mark A. Benson, MD; John R. Haaga, MD; Martin I. Resnick, MD

• We retrospectively reviewed the roentgenographic and pathologic staging of 64 patients with renal cell carcinoma to assess the role of the various staging modalities (ie, angiography, venacavography, bone scanning, ultrasound, computed tomography [CT], and magnetic resonance imaging). Specific attention was directed at detecting vena cava thrombus and metastatic bone disease, factors with a significant impact on the therapeutic approach. The findings support the role of CT as the principle tool for overall staging and the observation that venacavography is not indicated if CT has excluded caval thrombus. Similarly, routine bone scans are not warranted in the absence of an elevated alkaline phosphatase level or bone pain. The key to the more efficient utilization of imaging resources is understanding the capabilities of the technology available.

(*Arch Surg* 1989;124:71-73)

The development of several noninvasive imaging modalities (ie, ultrasound [US], computed tomography [CT], and magnetic resonance imaging [MRI]) has resulted in a debate over which or how many studies are indicated in the staging of patients with renal cell carcinoma.[1-5] Pressures to use resources more efficiently and contain medical costs argue against tests that provide redundant information, increase patient morbidity and expense needlessly, and do not have a significant impact on clinical management. Valid questions include (1) what is the role of former staging studies (ie, angiography or bone scanning), (2) when is venacavography indicated, and (3) will MRI replace CT as the current imaging standard? These issues require consideration to achieve a rational pattern of data collection before urologic intervention. No one study can possibly provide complete staging information in every instance. Prevention of wasted time and effort demands understanding the capabilities of the technology available to maximize study yield and facilitate appropriate evaluation and treatment.

In this study, we addressed these issues through a retrospective analysis of the radiographic staging of patients with renal cell carcinoma, comparing the preoperative clinical staging with the intraoperative and postoperative pathologic findings. The questions specifically asked were as follows: (1) Is venacavography indicated when CT has excluded caval thrombus? (2) Are routine bone scans warranted in the absence of chemical or clinical signs of metastatic disease? With respect to the diagnosis and delineation of caval thrombus, we also reviewed our experience with MRI, comparing the accuracy and correlation of its findings with the CT interpretation of the particular patient. The findings are discussed in light of previous studies and criteria suggested for imaging selection.

METHODS

The medical charts of 64 patients with a discharge diagnosis of renal cell carcinoma were obtained from the records of University Hospitals of Cleveland, Cleveland Metropolitan General Hospital, and the Veterans Administration Hospital, Cleveland, from 1981 through 1987. The following information was retrieved and recorded: (1) patient age and sex; (2) type and interpretation of diagnostic studies; (3) admission laboratory values (including hematocrit, creatinine, serum urea nitrogen, aspartate aminotransferase, lactate dehydrogenase, alkaline phosphatase, and calcium); (4) presenting symptoms (including gross hematuria, pain, weight loss, and abdominal mass); (5) intraoperative findings; and (6) pathologic diagnosis (gross and microscopic). Only patients with complete pathologic, surgical, and radiologic reports were included to ensure uniformity of data collection and reporting. The information was tabulated and grouped according to pathologic stage (Robson classification)[6] to assess for trends with increasing volume of disease.

RESULTS

In Table 1, the characteristics of the patient population are depicted as outlined above. The findings correlate well with several documented features of renal cell carcinoma (ie, male sex preponderance, peak incidence in the sixth decade of life, broad distribution of presenting symptoms, and lack of a specific chemical indicator of disease).[7] No specific correlation between the number of diagnostic studies obtained and the pathologic stage was noted. Although fewer studies might be expected in patients with metastatic disease, the data reflect the inclusion of several patients who underwent planned chemotherapy following radical nephrectomy before its ineffectiveness was demonstrated. Significant positive correlations were noted between pathologic stage and symptoms of pain and alkaline phosphatase levels, and a negative correlation with hematocrit values.

The overall staging accuracy of CT in the study is depicted in Table 2, which gives the percentage of correctly identified staging measurements (ie, local extension, nodal disease, and renal vein and vena cava involvement), false-positive results, and false-negative results. In the 57 patients undergoing CT, vena cava and renal vein thrombus was excluded in 47 instances, nodal disease in 51, and local extension in 52. All eight vena cava and renal vein thrombi were identified, with only two false-positive results. For local extension and nodal spread determinations, there were three and five false-positive results and two and one false-negative results, respectively. The false-negative findings involved cases of focal microscopic extension and micrometastases only, not gross disease.

In the six patients undergoing MRI, the interpretation of the studies was equivalent to the CT diagnosis. No false-negative results were noted with respect to renal vein or vena cava thrombus. The same thrombus false-positive findings were encountered using both CT and MRI. Comparisons could not be made for false-positive or false-negative findings of local extension and nodal disease due to the limited number of studies.

Table 1.—Demographics of Patient Population: Presenting Symptoms, Admission Laboratory Values, and Diagnostic Studies

	Pathologic Stage			
	I	II	III	IV
Patient Population				
No. of patients	25	5	12	23

Table 2.—Accuracy of CT Staging*

Pathologic Stage	Tumor Location (R/L)	No. of CT Scans	% Correct				False-Positive/ False-Negative Results
			Renal Vein	IVC	Nodes	Extended	
I	13/12	25	100	100	100	91	2/0
II	3/2	5	100	90	60	60	3/2
III	7/4	11	100	91	82	100	2/1
IV	13/10	16	100	94	94	94	3/0

*CT indicates computed tomographic; IVC, inferior vena cava.

Table 3.—Bone Scan Findings Correlated With Alkaline Phosphatase Levels and Bone Pain

Pathologic Stage	No. of Scans	Elevated Alkaline Phosphatase Levels (n = 115)	Bone Pain	Abnormal Bone Scan
I	17	3	10	0
II	3	3	3	0
III	10	5	3	. . .
IV	20	13	16	15

In the 35 patients undergoing invasive contrast studies (ie, angiography, venacavography, or both), thrombi were excluded in 25 instances and identified in six of eight patients. There were two false-positive and two false-negative results (involving renal vein thrombi). Local extension and nodal disease were not evaluated or mentioned in the majority of cases.

The bone scan findings correlated with the alkaline phosphatase levels and bone pain symptoms are illustrated in Table 3. Of the 50 patients undergoing study, no abnormal scans were found in patients with stage I and II disease. In the 15 instances of abnormal scans, all patients had either bone pain, an elevated alkaline phosphatase level, or both. The only equivocal case involved a patient with a small scapular hot spot suspicious for metastasis but not amenable to biopsy. This patient was followed up after radical nephrectomy, and the lesion remained unchanged for at least one year.

COMMENT

The staging techniques for patients with renal cell carcinoma have changed dramatically over the last decade with the evolution of the current imaging modalities. During the 1960s and 1970s, renal tumors were often identified by intravenous urography during the evaluation of patients with hematuria and abdominal masses. Nephrotomography, renal arteriography, and bone scans were typically performed to rule out local extension, nodal disease, and bone metastases in preparation for radical nephrectomy. Several studies, however, documented the deficiencies of arteriography with respect to identifying parameters other than vascularity. Bracken and Jonsson[8] and Futter et al[9] reported overall angiographic staging accuracies of only 36% to 44% and thought the use of the venous phase to determine the presence of thrombus was inadequate. Equivocal renal vein or vena cava involvement relied on venacavography for definitive confirmation. (Although occurring in only 3% to 7% of patients undergoing surgery for renal carcinoma, vena cava thrombus represents an important variable in determining the appropriate surgical approach, thereby helping decrease intraoperative morbidity.[4])

When US and CT ushered in the noninvasive imaging era in the mid-1970s, the roles of angiography and venacavography began to change. Although for many angiography arguably provided a preoperative road map, the overall

staging accuracy of US and CT was clearly superior, generally in the range of 70% to 90%.[1,10] In addition to improved staging, morbidity secondary to bleeding, embolism, subintimal injection of contrast, vessel perforation and thrombosis, and catheter or wire breakage (total average incidence, 0.5%) could be avoided. Ultrasound represented a safe, inexpensive, rapid, radiation-independent imaging alternative with potential as a screening tool. Unfortunately, operator or machine dependency and imaging distortion secondary to bowel gas and fat have limited its generalized applicability.[5] Computed tomography became the staging standard by virtue of (1) clearer definition of local extension, nodal disease, and caval thrombus under most circumstances; (2) reproducibility of studies; and (3) ease of interpretation.[1,3,11] Despite these advantages, during the late 1970s and early 1980s several centers continued to advocate CT, arteriography, and venacavography for all patients with renal cell carcinoma.[4]

Through the 1980s, continued improvements in CT technology have further supported its role in staging. Most studies, including the current one, report an overall staging accuracy of 90% to 95%.[3] Such data question the need for routine angiography and venacavography in cases where the lesion is clearly confined by Gerota's fascia and enhances with contrast medium. Equivocal cases, involving avascular masses, questions of extension into the liver, and suggestion of vena cava thrombus, warrant further workup to guide management (ie, either using invasive studies with contrast medium or MRI).

With the advent of MRI in the mid-1980s, the role of CT has been challenged. Proponents have emphasized the superiority of MRI in the delineation of tissue planes, the detection of caval thrombus, and even tissue diagnosis, with a reported accuracy of 96%.[2,12] Their results for CT were only 70%, contrary to the prevailing data. Importantly, their series failed to control for study technique or contrast administration. By incorporating variable quality scans from several institutions for CT but not MRI, their figures may not be representative and their conclusions therefore are suspect. None of the known limitations of MRI were observed, including a 1% to 5% incidence of claustrophobia and artifact secondary to motion. Controlling for operational, technique, and machine variables, one would anticipate comparable accuracy for each modality. In our study, cases where CT and MRI were performed jointly had equivalent interpretations, including a false-positive reading for caval thrombus. Others have had similar experience. Further research is indicated before replacing CT with MRI as the initial staging modality.[13]

On the basis of availability of resources, overall staging accuracy, expense, noninvasiveness, low morbidity, and experience, CT remains the first choice in the initial evaluation of patients with known or suspected renal cell carcinoma. For masses detected on intravenous urography and suspected of being simple cysts, US confirmation with adherence to the specific criteria is sufficient (ie, through transmission, absence of internal echoes, and smooth wall with posterior enhancement).[7] Angiography by current consensus should be limited to (1) malignant neoplasms in a solitary kidney, where knowledge of the vascular anatomy before partial nephrectomy is essential; (2) equivocal cases where US, CT, or MRI is nondiagnostic, acknowledging that 10% of avascular masses represent tumor; and (3) extremely large tumors, where angioinfarction is contemplated before radical nephrectomy to aid in controlling the renal pedicle by allowing initial ligation of the renal vein. Is venacavography indicated when CT has excluded thrombus? The data suggest that CT is more than adequate in determining the presence of renal vein or caval thrombus, as no false-negative results were encountered. Venacavography, MRI, or both should be reserved for equivocal cases, studies with abnormal results, or in instances of suspected extension beyond the hepatic veins, where thorough delineation of the thrombus is critical in determining the appropriate surgical approach.

Bone scans have traditionally been part of the metastatic workup due to the importance of detecting spread before surgery, as the prognosis is not improved by radical nephrectomy in this setting. With increased sensitivity over plain film and the potential for earlier detection of disease, nuclear bone scans would seem to be an appropriate screening tool. Previous studies, however, have suggested that in the absence of bone pain or an elevated alkaline phosphatase level, bone scans provide a low yield.[14,15] Although useful for confirming clinically or roentgenographically suspected metastases, staging or treatment plans were not significantly altered. Our findings indicated no abnormal scans in lower stage disease and, using the criteria above for obtaining scans, no instances of metastatic disease would have been missed. We agree with the assertion that routine bone scans are not warranted and should be reserved for patients in whom spread is suggested on chemical or clinical grounds.

Discussion

Q What are the indications for venography and angiography in evaluating patients?

A Generally it is well recognized that renal vein and, particularly, caval involvement are much more common with right-sided tumors. There have been reports in the literature that have placed criteria on when venocavography should be performed, particularly on right-sided tumors based on size and location in the kidney, ie, centrally located lesions; however, we did not find that and did not find it necessary to define our patients as having right- or left-sided tumors. We have obtained arteriograms in patients in whom we've had trouble diagnosing retroperitoneal tumors, but we generally have not found it to be useful. Many of these tumors have low vascularity. With renal tumors, I've mentioned angioinfarction, but I think many urologists today believe that angioinfarction is probably not that helpful in performing a radical nephrectomy, particularly for the larger tumors.

Photodynamic Therapy for Esophageal Tumors

James S. McCaughan, Jr, MD; Thomas A. Nims, MD; Jerry T. Guy, MD; William J. Hicks, MD; Thomas E. Williams, Jr, MD; Leslie R. Laufman, MD

• Between 1982 and 1987, 40 patients with esophageal tumors (19 adenocarcinomas, 19 squamous carcinomas, and two melanomas) in whom conventional treatments were unsuccessful were treated with photodynamic therapy (PDT) after injection with either hematoporphyrin derivative or dihematoporphyrin ether. Patients underwent endoscopy again two to three days and one month after PDT and as needed when symptoms recurred. At one month, the average minimal diameter opening of 28 assessable tumors increased from 6 to 9 mm. Of the 35 patients who could be evaluated one month after PDT, the average improvement in food intake was from a liquid to a soft diet. Average survival time (from time of first treatment) was 7.7 months (n=17) for adenocarcinoma, 5.8 months (n=12) for squamous cell carcinoma, and 25 months (n=2) for melanoma. Two patients with stage I adenocarcinoma were alive with no evidence of disease at 11 and 23 months. One patient with stage I squamous cell cancer died 18 months after PDT, with recurrence of tumor above the treated area noted eight months after treatment. One patient with stage I melanoma died of a synchronous colon cancer 31 months after PDT, with no evidence of residual melanoma.

(*Arch Surg* 1989;124:74-80)

Despite the various methods of treatment that have been attempted in patients with esophageal tumors, the prognosis remains poor. Regardless of the therapy, less than 4% of patients achieve five-year survival, and in 50% of these patients, the disease is unresectable when patients are first seen.[1] Chemotherapy, ionizing irradiation, or both may achieve some temporary relief, but the tumor frequently recurs with obstruction within six months.[2-5] Overall, surgical procedures carry an operative mortality approaching or exceeding 15% to 20%, with a mean survival frequently of less than six months.[6-9] Prosthetic intubation results in a mortality of 10% to 15%, with survival ranging only from two to four months. Solid foods usually cannot be eaten, and a complication rate of 25% can be expected.[10-14] Thus, most of our efforts are aimed at improving the ability of these patients to swallow and at improving their dietary intake for their few remaining months.

In 1978 Dougherty et al[15] reported success in treating cutaneous and subcutaneous malignant neoplasms with photodynamic therapy (PDT). The rationale for this treatment was that malignant neoplasms presensitized with hematoporphyrin derivative (HpD) can be selectively destroyed by exposing them to 630-nm light. Later, in 1984, Dougherty et al[16] reported that they had created a new dye by the fractionation of HpD and separation of a submixture. This product is designated dihematoporphyrin ether (DHE) (Photofrin II) and contains the active component of the HpD mixture. The efficacy of PDT has been demonstrated by several investigators treating many different kinds of malignant neoplasms, including melanomas of the choroid,[17-19] breast, skin, and subcutaneous metastases,[20,21] head and neck cancers,[19,22] bladder tumors,[23,24] gastric cancer,[25] tumors of the female genital tract,[19,21,26,27] primary skin cancers,[19,28] lung cancers,[19,29-31] and various other cancers.[21] In 1986, Dougherty's[32] review of the world literature stated that over 3000 patients had been treated with PDT.

We previously reported on our experience with HpD in the treatment of esophageal tumors.[33,34] This report is an update and expansion of those earlier studies, which employed both HpD and DHE as sensitizers.

PATIENTS AND METHODS

Forty patients (33 men and seven women) with esophageal malignant neoplasms (19 adenocarcinomas, 19 squamous cell carcinomas, and two melanomas) were treated with PDT between November 1982 and August 1987. The average patient age was 68 years (range, 54 to 88 years). All patients had received, were ineligible for, or had refused conventional surgery, ionizing radiation, or chemotherapy. The goal of the therapy was to facilitate swallowing; therefore, no patient was refused treatment because of their clinical status (Table 1).

All patients were hospitalized from at least the time of their injections until at least three days after their PDT sessions. Patient histories were obtained and patients underwent complete physical examinations. Barium esophagograms, computed tomographic scans of the chest and abdomen, liver and spleen scans, posteroanterior and lateral chest roentgenograms, complete blood cell count, blood chemistry studies, and urinalysis were performed. Clinical staging was done according to the *Manual for Staging of Cancer*,[35] which is related to tumor stage and presence of distal metastases, since regional nodes cannot be examined clinically. Staging was as follows: T1M0, stage I; T2M0, stage II; T3M0, stage III; and M1, stage IV.

A total of 85 PDT sessions were completed, 36 after a total of 28 injections of 3 mg/kg of HpD and 49 after a total of 45 injections of 2 mg/kg of DHE. After injection of the sensitizer, vital signs were taken every six hours, and daily complete blood cell counts, blood chemistry studies, and urinalyses were performed until the patient was discharged from the hospital. Daily chest roentgenograms were taken after PDT until the patient was discharged from the hospital.

Endoscopy

The PDT was performed usually on the third day after injection of the sensitizer (range, one to six days). Patients underwent endoscopy again two to three days and one month after PDT and as needed when symptoms recurred. All endoscopies were performed with topical anesthesia and intravenous sedation. Tumor length and the minimal diameter opening were estimated by direct flexible endoscopy. The tumor site and length were recorded as centimeters from the teeth. The diameter of the minimal opening was estimated with the use of open biopsy forceps of known diameter. Biopsies and brushings for cytologic examination were routinely performed. Still photographs were taken and videotapes made to document the effect of treatment. All PDT sessions and follow-up endoscopies were performed by one of us (J.S.M.).

Light Source and Dose

A tunable dye argon laser system (Spectra Physics) delivered 630 ± 2-nm light through a 400-μm quartz fiber inserted down the biopsy channel of the flexible endoscope. Initially rhodamine B dye was used for the dye laser, but for the past three years we have used kiton red dye.

Originally, we used a straight-tip fiber. The power output from these fibers was measured with a radiometer (Coherent 210). For surface treatment with straight-tip fibers, the light dose was

estimated as joules per square centimeter of tissue from the time of exposure, the power delivered from the tip, and the area of the tumor exposed. Straight-tip fiber interstitial (inserted into the tumor) light dose could only be estimated as the total number of joules delivered from the power output and the time of insertion. Later, cylinder diffusing fibers were used to deliver the light perpendicular to the longitudinal axis over 1 to 2 cm. The power per centimeter was measured by dividing the total power measured with an integrating sphere radiometer by the length of the diffusing tip. Cylinder fiber light dose (surface and interstitial) was estimated as joules per centimeter of fiber from the power delivered per centimeter of diffusing fiber and the time of exposure. Tumors longer than the diffusing cylinder were treated by sequentially moving the fiber the length of the diffusing fiber.

Follow-up

Follow-up was achieved on 100% of patients. Each patient's ability to swallow was evaluated, and the cause of death was determined either by direct evaluation or by personal communication with the patient, family, and/or referring physician. Quality of life was evaluated by a comparison of baseline and one-month posttherapy measurements of Karnofsky performance status (KPS), weight, and diet. An esophageal grading system[36] was also used to evaluate the patient's quality of life. This system assigned a numerical grade based on the patient's swallowing ability (45%), pain type and severity (40%), ability to sleep (6%), leisure activity (5%), and work status (4%). The esophageal grades for swallowing ability were as follows: no ability to swallow, 0; clear fluids only, 15; blenderized foods, 25; most soft foods, 35; and regular food, 45.

RESULTS

Effect of Injection of Sensitizer

No clinical side effects were noted after injection of either HpD or DHE, including changes in vital signs or development of allergic responses.

Tumor Response

One month after treatment, 28 tumors (15 adenocarcinomas, 11 squamous cell carcinomas, and two melanomas) were assessable (Table 2). The remaining tumors could not be assessed either because of patient death or because the patient was doing well, lived several hundred miles away, and declined to return to our center for examination. At one month, the average length of the 15 adenocarcinomas had decreased from 9 to 7 cm, and the average minimum diameter opening had increased from 6 to 9 mm. The average length of the two melanomas had decreased from 5 to 3.5 cm, and the average minimum diameter opening had increased from 11 to 13 mm. The average length of the 11 squamous tumors had decreased from 6 to 5.3 cm, and the average minimum diameter opening had increased from 6 to 9 mm. Overall, the average length had decreased from 7.0 to 6.1 cm (not significant), but the average minimal diameter opening had increased from 6 to 9 mm ($P<.001$ by Student's t test).

Patient Survival

Thirty-one of 40 patients were assessable after the first PDT (17 adenocarcinomas, 12 squamous cell carcinomas, and two melanomas). Nine patients were excluded for the following reasons: three had preexisting tracheoesophageal fistulas (patients 28, 34, and 36); one committed suicide two weeks after PDT (patient 40); one with disseminated metastases had a saddle pulmonary embolus four days after PDT (patient 38); one had a mechanical perforation by the esophagoscope (patient 10); one patient who had previously had a complete obstruction died of aspiration pneumonia from gastrostomy tube feeding after PDT (patient 11); one patient died of synchronous obstructive lung cancer (patient 27); and one patient died of a preexisting leakage in the jejunostomy tube (patient 37) (Table 1). The average survival from the first PDT was 7.7 months for the 17 patients with adenocarcinoma, 5.8 months for the 12 patients with squamous carcinoma, and 25 months for the two patients with melanoma.

Figure 1 depicts the average survival time as a function of the clinical stage determined at the time of the first PDT session. The average survival for patients with stage I adenocarcinomas (two tumors) was 17 months. Two of these patients had complete response of the treated area and remained alive with no evidence of disease at 11 and 23 months. Survival for one patient with stage I squamous carcinoma was 18 months. This patient developed recurrence above the treated area eight months after the first PDT session but had no recurrence of the tumor in the treated area. Survival for one patient with stage I melanoma was 31 months. The patient died of synchronous carcinoma of the colon with no evidence of melanoma.

The average survival for patients with stage II adenocarcinoma (ten tumors) was 8.4 months. Two of these patients remained alive with residual disease five and 11 months after their first PDT sessions. Patient survival for

Fig 1.—Average survival time as related to clinical stage determined at time of first photodynamic therapy. NED indicates no evidence of disease.

stage II squamous carcinoma (four tumors) was 7.9 months; for stage II melanoma (one tumor) patient survival was 19 months.

Average survival for stage III tumors was 4.5 months for adenocarcinoma (one tumor) and 3.4 months for squamous carcinoma (five tumors). Stage IV survival was 2.1 months for adenocarcinoma (four tumors) and 1.4 months for squamous carcinoma (two tumors) (Figs 2 through 8).

Quality of Life

Thirty-five patients were assessable one month after their first PDT sessions. Quality of life was assessed according to changes in weight, KPS, esophageal grade, and diet. The KPS and weight remained essentially unchanged, the former increasing from an average of 62 to 66 and the latter decreasing from an average of 65.7 to 64.4 kg, but the esophageal grade and particularly the diet grade improved. The esophageal grade increased from an average of 59 to an average of 75. The average diet grade increased in one month from 16 to 32, which represents improvement from a liquid to a soft diet ($P<.001$ by Student's t test).

Nine patients had complete obstruction when first treated. They survived an average of three months (range, one to 11 months). One month after treatment, two patients had died, one was eating a regular diet, two were tolerating a soft diet, and four patients were tolerating a liquid diet, for an average diet grade of 23 (equal to a blended diet). At the time of their deaths, one patient was eating a regular diet, three patients were maintained on soft diets, four patients could tolerate liquid diets, and one patient could swallow only saliva.

Complications

There were no allergic responses to any of the injections. The highest average temperature at the time of PDT after injections in 58 afebrile patients was 36.9°C; the highest average temperature after PDT was 37.4°C, occurring an average of two days after therapy. The average white blood cell count of these patients before injection was 8×10^9/L and was 11×10^9/L one day after PDT. The average highest white blood cell count of 14×10^9/L occurred an average of three days after PDT.

The maximum amount of bleeding at any PDT endoscopy was characterized as oozing. One patient suffered a mechanical perforation of the esophagus by the esophagoscope at the junction of the proximal end of the tumor and the normal esophagus, but this was unrelated to the PDT.

Edema with decreased lumen was frequently noted at repeated endoscopy two to three days after PDT. This often was seen developing in areas at the end of the treatment. Occasionally, the edema exacerbated difficulty in swallowing, but the tumor was soft and easily dilated.

Nine of the 85 treatments caused pleural effusions in six patients. All cleared except in one patient (patient 20), who required bilateral chest tubes and a subsequent thoracotomy to ligate the thoracic duct for chylothorax.

Six strictures occurred in five patients. All were manageable by dilation. Three were associated with development of pleural effusion and three were not.

Three patients developed tracheoesophageal fistulas. In one case, this was probably unrelated to the PDT because the patient (patient 30) already had invasion of the trachea, and the fistula did not occur for several weeks. A second patient (patient 33) who developed a fistula had undergone a previous esophageal reconstruction skin graft and tracheostomy 12 years earlier for cancer of the larynx. The third patient to develop a fistula (patient 13) had an adenocarcinoma that had spread along the esophagus rapidly after the patient underwent radiation therapy.

In most patients, solar photosensitivity is a possible complication for at least one month after injection. Four

patients developed gradual reddish brown discoloration of the exposed skin that lasted for several months. One patient sustained third-degree necrosis of a 2-cm-diameter area of his hand when he fell asleep with sun coming through the window eight weeks after his first injection of DHE. Nevertheless, these minor complications do not seem to offer too great a handicap for patients who are more than willing to trade the sunlight for the ability to swallow.

COMMENT

The survival rate of patients with cancer of the esophagus continues to be poor, regardless of the type of treatment. Morstyn et al[37] reported an average survival of three to four months in 71 patients with esophageal tumors who did not undergo surgery. In comparison, the average survival from the time of diagnosis of eight patients in our study with squamous carcinoma and adenocarcinoma who did not have any previous treatment was 11.4 months. Of 19 patients who had undergone previous forms of therapy (including six patients who had undergone x-ray therapy), average survival was 10.9 months. One patient with stage I melanoma died 31 months after his first treatment, with no evidence of disease. A patient with stage I squamous cell cancer had a complete response for eight months and then developed tumors similar to those previously treated above the treated area. A patient with stage I adenocarcinoma was alive with no evidence of disease 23 months after therapy. It should be noted that there was no correlation between length of survival and the length of the tumor or the minimal diameter opening before treatment. Survival was independent of histologic type for adenocarcinoma and squamous cell carcinoma when tumors in the same clinical stage were compared (Fig 1). Direct endoscopy should always be used to evaluate the opening because contrast roentgenograms are frequently misleading. Adenocarcinomas were noted to progress longitudinally over time.

The most important factor in palliation for these patients is the ability to swallow. In this regard, neither KPS nor the esophageal grade alone is a reliable measure of the patient's condition or prognosticator of survival. Patients who are able to swallow may have a high esophageal grade but a low KPS due to metastases. On the other hand, patients with a low esophageal grade due to obstruction may have a high KPS because the tumor is still localized. It should be emphasized, however, that no patient with a combined total score of less than 120 on both the KPS and esophageal grade scales lived longer than six months after PDT. Having observed desperate patients with complete obstruction, we believe that the ability to swallow even one's own saliva is sufficient to justify therapy. The PDT was particularly effective in achieving this goal. One month after PDT, of nine patients who had had complete obstruction, one was eating a regular diet, two were able to tolerate soft diets, and four patients were on liquid diets. Two patients had died, but both had improved their dietary intake at the time of their deaths, one to a soft diet and one to a liquid diet. It should be mentioned, however, that despite improvements achieved by the therapy, some patients will not have an increased dietary intake because of anorexia. Thus, we now recommend the use of feeding gastrostomies because we can frequently control the problems caused by obstructed saliva by treatment with PDT or the neodymium:YAG laser.

Although several patients developed complications related to PDT, many other patients treated with similar light doses did not develop problems. We believe that the development of these complications depends on whether the treated area was encased with concentric tumor, in which case complications did not develop.

Technically, it is difficult to treat segments of the esophagus sequentially without overlapping treated areas, and it is this overlap that may create the stricture. One patient developed two separate, discrete strictures after a treatment session, although the tumor area became smooth and tumor free (patient 22).

It is interesting that five patients in this study had a history of previous unrelated cancers. One patient had been diagnosed with cancer of the colon, one had developed cancer of the lung, and three patients had a history of cancer of the larynx. In addition, three patients developed synchronous, unrelated cancers, one patient developing cancer of the colon and two patients developing cancer of the vocal cord.

It is imperative that patients undergo bronchoscopy before treatment. In this series, six patients had malignant invasion of the respiratory tract at the time of PDT. Two patients (one with adenocarcinoma and one with squamous carcinoma) had invasion of the left main bronchus. Four patients with squamous carcinoma had invasion of the trachea. In addition, we urge that symptomatic patients undergo esophagoscopy, even if barium swallow examinations are normal. In this study, four patients with stage I disease and one patient with stage II disease were found to have esophageal cancer despite their "normal" findings on barium swallow examination. One patient with stage II disease was reported to have a "benign stricture." On the other hand, three patients who in reality developed benign strictures after PDT were diagnosed as having cancer. Obviously, a definitive diagnosis can be made only if patients undergo both bronchoscopy and esophagoscopy.

Fig 2.—Stage II squamous carcinoma in patient 24 before treatment (left) and two months after photodynamic therapy (right). Diet improved from clear liquids to regular food.

Fig 3.—Barium swallow study in patient 24 with squamous carcinoma before (left) and two months after (right) photodynamic therapy. Patient had gained 7.7 kg and was eating a regular diet.

Fig 4.—Esophageal melanoma in patient 21 before (left upper corner), during (right upper corner) (with the fiber in place), and three weeks after (left lower corner) photodynamic therapy. Patient improved from liquid to regular diet. He was treated seven times and survived 19 months after first treatment, during which time he ate a regular diet.

Fig 5.—Adenocarcinoma in patient 9 before (left) and three days after (right) treatment. Patient improved from clear liquid diet to soft diet. He received two treatments and was alive and on regular diet ten months after first treatment.

Fig 6.—Stage I adenocarcinoma in patient 2 before (left upper corner) and during (right upper corner) treatment with interstitial fiber and one month after first treatment (left lower corner). Patient was reinjected and retreated with surface technique and was alive 19 months after first treatment, with no evidence of disease (right lower corner).

Fig 7.—Adenocarcinoma in patient 14 causing complete obstruction before (left upper corner) and two days after (right upper corner) surface photodynamic therapy, showing opening of obstruction and reaction. Two months after (left lower corner) therapy, patient was eating a regular diet. He died 11 months later of myocardial infarction. He had received six treatments and was eating a regular diet at time of death.

Fig 8.—Adenocarcinoma in patient 12 before (left) and two days after (right) photodynamic therapy. Patient was alive five months after first treatment and continued to eat a soft diet.

Discussion

Q How long do you keep them out of the sun?

A We tell them to stay out of the sun for a month; we have a whole procedure we go through. We give them lectures and slide shows. Some of them don't believe us, and they go out and get a bad sunburn. We've had three patients of about 250 who have had to be admitted because of severe sunburn and are given corticosteroids, but most of the time it will subside, and we tell them to go out in the evening. They use factor 33, which will take care of the ultraviolet, but it won't protect them completely. Usually after a month, they can start going out slowly. The man who got sunburned in six months got it through his shirt, but he had recurrent disease in his bronchial stump that we treated and he is now almost three years, with no recurrence. He got sunburned playing golf six months after he had been treated, on a bright sunny day; maybe you figure, well, that's not much of a price to pay.

Q In operable esophageal cancer, does this have any role as initial therapy prior to surgery?

A The question is, would this be good preoperatively for somebody with cancer of the esophagus to try to open them? I think probably if you wanted to do that, you'd go ahead with a laser, but I don't know that there would be much point in doing it, myself.

Q Let's speak to the issue of using this treatment as primary therapy. You did have a patient or two in the esophageal group who went for a long period of time, and you also had some individuals, who died of other causes disease free. What about the use of the treatment as primary therapy?

A Well, this is investigational therapy, and we don't do this on anybody, unless they have had everything else. They're not candidates for it until it's approved by the Food and Drug Administration, for both legal and ethical reasons. Our patients, for example, a 77-year-old man who previously had a triple bypass, are not candidates for surgery. We have used PDT for patients with lung cancer who have had bilateral disease and small tumors. We treated one and got a complete response; then he had the other lobe out. That's been a year and there's no evidence of recurrence.

Q How do you decide on the dose of light?

A If you give enough light to any of the tissue, you will get a burn. You can think of this like x-ray therapy. You get too much, you get burned. Its just a different wavelength. And that is what we've been trying to figure out; what's the right light dosage?

Q On the basal cell carcinomas that you've previously treated on the face, do you treat them again, and how long do you have to wait?

A We have treated one patient with recurrence in his sacrum. We gave him a total of ten injections and 16 treatments over 2½ years, and we've had no problems with accumulation. Now, he has sort of a yellowish cast to his skin. I had another patient who had a Klatskin tumor. We put a U-tube in, and I treated her with endoscope. I went back for the third time. I passed my endoscope right into the tumor. She is now three years after treatment. The point is that you can inject this stuff over and over again and treat them over and over again.

Q Can you do this with oral cancer?

A Yes, it will work for small tumors. The one patient we treated had a previous laryngectomy. Then he had a tumor on his soft palate and we treated him, shining the light there for eight minutes. In two years there was no evidence of recurrence of that tumor. Again, these people had had every other treatment or we won't touch them. He died from his other metastases.

Effect of Timing of Lymphokine Presentation on Generation of Cytotoxic T Lymphocytes

Monica M. Stringfellow, MD; Richard E. Wilson, MD; Steven J. Burakoff, MD; Steven H. Herrmann, MD

• Encouraging results of clinical trials with interleukin 2 therapy for advanced malignant neoplasms have led to efforts to reduce the toxicity and improve the efficacy of tumor immunotherapy. To begin to achieve this goal, we studied the lymphokine requirements for in vitro generation of polyclonal cytotoxic T lymphocytes (CTL) from C57BL/6 murine thymocytes. We found that both interleukin 2 and interleukin 6 are required for optimal generation of CTL from murine thymocytes. Timing studies show that neither lymphokine alone in culture will produce maximum CTL levels during the first 84 hours of culture. In addition, we found that thymocytes cultured with concanavalin A are unresponsive unless either interleukin 2 or interleukin 6 is present from the onset of culture.

(*Arch Surg* 1989;124:81-84)

The encouraging results of clinical trials with interleukin 2 therapy for advanced malignant neoplasms raise the hope that exogenous lymphokines may be useful in augmenting host responses to tumor. Promising work in adoptive immunotherapy involves the in vitro generation of specifically sensitized T lymphocytes to mediate tumor regression in vivo.[1-4] It is important, therefore, to know the lymphokine requirements for generation of cytotoxic T lymphocytes (CTL) both in vitro and in vivo to reduce the toxicity and improve the efficacy of tumor immunotherapy.

The required sequence of molecular events leading to tumor-specific CTL development is unknown. The induction of CTL from precursor T cells requires transmembrane signals generated through both the antigen-specific T-cell receptor and lymphokine receptors.[5,6] Previous studies indicate that multiple lymphokines are required for T-lymphocyte activation. Depending on the assay system, interleukin 2 (IL-2), interleukin 6 (IL-6), interleukin 4 (IL-4), and interferon gamma have all been implicated in T-cell differentiation and activation.[7-12] Interleukin 2 is generally associated with T-cell proliferation, while IL-4 and IL-6 have been associated with the differentiation of B lymphocytes and with the differentiation of T cells, as indicated by the generation of a cytotoxic response and the expression of serine esterase activity.[8,12-14] The exact role of these lymphokines in CTL maturation and activation has not been established. The multiple lymphokine requirement for differentiation of thymocytes into CTL suggests that a cascade type of regulation may be involved. Signaling by one lymphokine may influence the effect of a second by inducing required lymphokine receptors or causing the production of final lymphokine mediators.[8,11,13]

In our assay system, a murine whole thymus preparation was cultured with concanavalin A (ConA) in the presence of various lymphokines; after a two- to four-day culture the polyclonal CTL response was measured by the lysis of P815 tumor cells in the presence of phytohemagglutinin. A first step in assigning lymphokine function is to define the lymphokine requirements under different culture conditions and to ask if there is a specific temporal order for addition of the necessary lymphokines. We have found evidence that, over a four-day incubation period, the cytotoxic response generated by thymocytes cultured in IL-2 plus IL-6 was greater than the response generated by culture in either alone; that thymocytes cultured in the absence of exogenous lymphokines rapidly lost the ability to generate a cytotoxic response; and that this exogenous lymphokine requirement could be fulfilled by either IL-2 or IL-6.

MATERIALS AND METHODS

Animals and Cell Lines

C57BL/6 and (BALB/c × DBA/2)F_1 female mice 6 to 8 weeks of age were purchased from The Jackson Laboratory, Bar Harbor, Me. P815 (H-2^d mastocytoma) was maintained by weekly passage as ascites in (BALB/c × DBA/2)F_1 mice.

Lymphokines

Human recombinant IL-2 was purchased from Amgen Biologicals, Thousand Oaks, Calif. Human recombinant IL-6 was produced in COS cells and purified to homogeneity.[15]

Accepted for publication Sept 21, 1988.

From the Department of Surgery, Brigham and Women's Hospital and Harvard Medical School (Drs Stringfellow and Wilson), and the Departments of Pediatrics and Pathology, Division of Pediatric Oncology, Dana Farber Cancer Institute and Harvard Medical School (Drs Burakoff and Herrmann), Boston.

Read before the Annual Meeting of the Society of Surgical Oncology, New Orleans, May 23, 1988.

Reprint requests to Department of Surgery, Brigham and Women's Hospital, 75 Francis St, Boston, MA 02115 (Dr Stringfellow).

Fig 1.—Dependence of thymocytes on interleukin 6 for cytotoxic T-lymphocyte generation is function of fetal calf serum used in culture. Circles indicate cells cultured in interleukin 2 plus interleukin 6; triangles, cells cultured in interleukin 2 alone.

Fig 2.—Level of cytotoxic T lymphocytes generated by addition of interleukin 2 alone (broken line) compared with that generated by addition of interleukin 2 plus interleukin 6 (solid line). Effector cells were 8×10^5 per well C57BL/6 thymocytes plus 3 mg/L of concanavalin A. Bars indicate arithmetic mean ± SD ($P<.01$ for all points by Student's *t* test).

In Vitro Culture for CTL Generation

Whole thymocytes from 6- to 8-week-old C57BL/6 mice were prepared as described previously.[7] Eight hundred thousand thymocytes were cultured in 96-well, round-bottomed microtiter plates in the presence of 3 mg/L of ConA (Sigma Chemical Co, St Louis). Where indicated, IL-2 (20 U/mL) or IL-6 (100 ng/mL) were added either together or singly at defined intervals of time. Total culture time varied from 48 to 84 hours, as indicated. The culture medium consisted of RPMI 1640 supplemented with 100 U/mL of penicillin, 100 mg/L of streptomycin, 2 mmol/L of glutamine, and a selected lot of 5% heat-inactivated fetal calf serum (FCS).

It became apparent that the lymphokine requirements were dependent on the lot of FCS used in thymocyte culture. Figure 1 compares two different lots of FCS. In FCS lot A, at a concentration of 5%, the level of CTL generated by IL-2 alone was 50%, as compared with 61% for IL-2 plus IL-6. In 5% FCS lot B, 10% lysis resulted from culture in IL-2 alone, compared with 33% lysis from the addition of both IL-2 and IL-6. This FCS, from Hyclone Labs, Logan, Utah, lot 1111649, was used for all work presented. It is likely that FCS from lot A contains bovine lymphokines functional on murine thymocytes or products able to induce lymphokine production by thymocytes.

CTL Assay

After completion of the culture interval, microtiter plates were centrifuged at 1000 rpm for five minutes, the culture medium was decanted, and 10^4 chromium 51–labeled P815 target cells and 10 mg/L of phytohemagglutinin-P (Difco Laboratories Inc, Detroit) were added to each well in a final volume of 200 uL. After a four-hour incubation at 37°C, cells were pelleted and an aliquot of supernatant was removed and counted in a gamma counter. The percentage of specific lysis was calculated as follows: [100 × (chromium 51 released with effector cells) − (spontaneous chromium 51 release)]/[(maximal chromium 51 released with 5% Triton X-100) − (spontaneous chromium 51 release)].

Fig 3.—Effect of delayed addition of lymphokine to C57BL/6 thymocytes plus concanavalin A. Total culture time in presence of interleukin 2 (IL-2) plus interleukin 6 (IL-6) was 48 hours. Total length of culture varied, as indicated in parentheses, from 60 to 84 hours. Bars indicate arithmetic mean ± SD ($P<.01$ for all points by Student's *t* test).

RESULTS

The IL-6 requirement for generation of a CTL response was demonstrated in previous work using lectin-triggered thymocytes and a 48-hour in vitro culture.[7,8] To determine if thymocytes cultured for longer periods also require non–IL-2 lymphokines, the level of cytotoxicity was determined after 48, 60, 72, and 84 hours of culture. Thymocytes cultured with the IL-2 plus IL-6 combination reached the highest level of target cell lysis, 55%, at 60 hours and remained at this level (Fig 2). Target cell lysis was negligible by thymocytes cultured for 48 hours with added IL-2; however, with increasing lengths of culture the level of lysis increased until at 84 hours 34% of target cells were lysed (Fig 2). With longer periods of incubation, as predicted from Fig 2, the level of lysis by thymocytes cultured in the presence of IL-2 only was similar to that found for IL-2 plus IL-6 (data not shown). A maximal cytotoxic response, therefore, was generated if both lymphokines were present for at least 48 hours of thymocyte culture.

Next we asked if IL-6 and IL-2 must be present from the initiation of culture to generate a cytotoxic response. When the addition of IL-2 or IL-6 to culture was delayed

Fig 4.—Effect of delayed addition of lymphokine to C57BL/6 thymocytes plus concanavalin A. Assays measured lysis of chromium 51–labeled P815 tumor cells after 84 hours of total culture time. Bars indicate arithmetic mean ± SD; IL-2, interleukin 2; and IL-6, interleukin 6 ($P<.01$ for all points by Student's *t* test).

Fig 5.—Effect of sequence of lymphokine addition on cytotoxic T-lymphocyte generation. Total culture time in presence of interleukin 2 (IL-2) plus interleukin 6 (IL-6) was 48 hours. Total length of culture varied, as indicated in parentheses, from 48 to 84 hours. Bars indicate arithmetic mean ± SD ($P<.01$ for all points by Student's *t* test).

12 or more hours, and the level of response was determined 48 hours after lymphokine addition, a CTL response of less than 5% lysis was observed (Fig 3). Figure 4 shows that addition of IL-2 and IL-6 together at 0, 12, 24, or 36 hours after the onset of culture with assay of cytotoxic activity at 84 hours resulted in 59%, 32%, 13%, and 3% lysis, respectively. Thus, delay of lymphokine addition for 12 hours resulted in significantly diminished CTL response. We then asked if both lymphokines must be present during thymocyte culture to prevent loss of lytic ability. The addition of IL-2 at the initiation of culture with IL-6 added 12, 24, or 36 hours later resulted in a response ranging from 45% to 67% (Fig 3). Cultures incubated with IL-2 or IL-6 alone for 84 hours resulted in 34% and 11% lysis, respectively (Fig 3). The levels of cytotoxicity for thymocytes cultured with IL-2 from the onset of culture with IL-6 added 0, 12, 24, and 36 hours later were all approximately 66% when assayed at 84 hours (Fig 4). Thus, thymocytes cultured in the absence of lymphokine quickly became nonresponsive, while thymocytes cultured with IL-2 became maximally responsive provided that IL-6 was added 48 hours before assay for cytotoxicity (Fig 4).

Experiments completed to this point indicated that thymocytes cultured in the absence of IL-2 for more than 12 hours were unresponsive to the cytotoxicity-generating effects of subsequent culture in IL-2 plus IL-6. We asked if maintenance of the thymocyte's ability to respond was dependent on culturing in IL-2, or if IL-6 would also satisfy the requirement for added lymphokine. Thymocytes were cultured in IL-2 or IL-6 and the complementary lymphokine added at 0, 12, 24, or 36 hours, with cytotoxicity determined 48 hours after addition of the second lymphokine. The addition of the complementary lymphokine at the different time points resulted in a CTL response ranging from 40% to 60% (Fig 5). Thymocytes cultured for 84 hours with either IL-2 or IL-6 alone gave 34% and 11% lysis, respectively. Thus, either IL-2 or IL-6 maintained lectin-triggered thymocytes in an active state and these thymocytes were able to generate a CTL response, provided the complementary lymphokine was added (Fig 5).

COMMENT

Recent studies indicate that a differentiation factor is required for thymic precursors to respond to IL-2 and give rise to functional CTL.[6-10] The evidence that IL-6 can support the differentiation of T cells into active CTL was obtained using a 48-hour culture of thymocytes triggered with ConA.[7,8] A long-term goal of these studies is to define the lymphokine requirements controlling the T-cell response to antigen. In this investigation, our first question was to determine if IL-6 was required when thymocytes were cultured for more than 48 hours in the presence of IL-2. Our results show that the response generated by IL-2 (20 U/mL) plus IL-6 (100 ng/mL) added at the beginning of culture was greater than the response generated with IL-2 alone for all time points tested between 48 and 84 hours (Fig 2). With increasing lengths of culture time (≥96 hours), the response to IL-2 alone approached that found for the combination of IL-2 and IL-6 (data not shown). Thus, for short culture periods, a very limited CTL response was found unless IL-6 was added. The generation of CTL on longer culture in the presence of IL-2 alone may indicate that, given sufficient culture time, non–IL-2 lymphokines are generated when thymocytes are cultured with IL-2, or a small population of cells respond to IL-2 alone and these cells proliferate during longer cultures to match the cytotoxicity generated by adding the combination of lymphokines. In other studies we found that for 48-hour cultures, a half-maximal CTL response was obtained with approximately 250 pmol/L of IL-6. Since many different cell types are able to produce IL-6,[16] it is possible that during extended periods of incubation sufficient IL-6 is produced to support the generation of CTL. Defining the exact lymphokine requirements for CTL generation under all culture conditions will require the ability to block the effects of specific lymphokines through the use of blocking antibodies or the development of specific antagonists.

Culturing of cloned cytotoxic T cells in the presence of

ConA alone has been shown to result in blocking of both antigen-specific and lectin-dependent cytotoxicity.[17] Our results indicate that culture of thymocytes in the presence of ConA but in the absence of added lymphokines results in thymocytes that are unable to become cytotoxic. In contrast, culturing in either IL-2 or IL-6 alone, while unable to generate a high-level CTL response, prevents the unresponsiveness to later addition of the complementary lymphokine. It appears that triggering thymocytes through the antigen-specific T-cell receptor or some other ConA binding site results in thymocyte inactivation unless lymphokines such as IL-2 or IL-6 are present.[17-19]

This study was supported in part by the National Cancer Institute (Bethesda, Md) National Research Service Award for Training in Surgical Oncology, T32 CA09535-04 (Drs Stringfellow and Wilson); Ethicon–Society of University Surgeons Surgical Research Fellowship (Dr Stringfellow); National Institutes of Health (Bethesda, Md) grants CA 47831 and SO7RR05526-24 (Dr Herrmann) and AI17258 (Dr Burakoff); and the American Cancer Society (Atlanta, Ga) Junior Faculty Award (Dr Herrmann). Human recombinant IL-6 was provided by Steven C. Clark, PhD, Genetics Institute Inc, Cambridge, Mass.

Discussion

Q Is the IL-2 generating CTL in a maturation pathway separate from that of IL-6?

A It has been suggested that in low doses such as those used in this study, IL-2 is responsible for maintaining the viability and stimulating the proliferation of T cells in vitro. Interleukin 6 was initially found to be an inducer of B-cell differentiation, and it is possible this lymphokine is also responsible for the differentiation of CTL precursors. If CTL generation is best accomplished by proliferation of a precursor population as an initial step, and then secondary differentiation of these cells to functional CTLs, then we would expect cells cultured in IL-2, followed by IL-6 at a later time, to generate greater CTL response than the cells that were presented lymphokine in the reverse order. Our results suggest that a synergy exists between IL-2 and IL-6 in the production of CTLs from thymocytes.

Q Are there any ways of determining by phenotypic markers that individual subsets of cells are being driven to become functional CTLs?

A One of the most difficult problems in CTL research is the identification and purification of T-cell subsets on the basis of phenotypic markers. Methods of selection available at this time use antibodies to cell surface proteins such as CD4 and CD8, but as these molecules also play a role in T-cell activation it is difficult to interpret the results obtained from these selections. We are presently involved with studies utilizing positive selection methods with monoclonal antibodies to cell surface proteins to fractionate the thymic population. We hope to be able to isolate the cell population responsible for the development of CTLs in the presence of IL-6.

Q What is the mechanism of the lectin-activated CTL killing?

A Two signals are required for the induction of CTL activity: stimulation of the T-cell receptor, and signal delivery through lymphokine receptors. Concanavalin A has been shown to bind to the T-cell receptor, providing a signal that, together with an appropriate lymphokine, results in antigen nonspecific target cell lysis. Concanavalin A also binds many other cell surface molecules, and the importance of this for CTL generation is not known. We have shown in other studies that CTLs generated in this lectin-dependent manner release serine esterase during target cell lysis, therefore correlating with antigen-specific target cell lysis with esterase release. We have also found that when irradiated allogeneic murine thymocytes are used instead of ConA to stimulate the T-cell receptor, the pattern of CTL activity in response to IL-2 and IL-6 is similar to that seen with ConA stimulation. This indicates that the ability of IL-6 to support the generation of CTL is not limited to triggering the T-cell receptor through lectin.

- ☐ Consistent activity** (virtually unchanged over time) against *Bacteroides fragilis*
- ☐ No MTT side chain

MEFOXIN is indicated for the treatment of intraabdominal, gynecological, lower respiratory tract, and skin and skin-structure infections due to designated susceptible organisms including members of the *Bacteroides fragilis* group. (See Brief Summary for complete listing of indications.)

MEFOXIN is contraindicated in patients who have shown hypersensitivity to cefoxitin and the cephalosporin group of antibiotics. Before therapy with MEFOXIN is instituted, careful inquiry should be made to determine whether the patient has had previous hypersensitivity reactions to cefoxitin, cephalosporins, penicillins, or other drugs. This product should be given with caution to penicillin-sensitive patients.

Pseudomembranous colitis, from mild to life-threatening in severity, has been reported with virtually all antibiotics (including cephalosporins); therefore, it is important to consider its diagnosis when diarrhea develops in association with antibiotic use.

(Cefoxitin Sodium | MSD)

*Percent susceptible at 16 mcg/mL: *B. fragilis* (91%), *B. thetaiotaomicron* (84%), *B. distasonis* (78%), *B. vulgatus* (88%), and *B. ovatus* (79%)—based on Antibiotic Susceptibility Reports, National Summary, in *The Bacteriologic Report: Volume I 1987*, Totowa, NJ, BAC-DATA® Medical Information Systems, Inc., 1987.

***In vitro* activity does not necessarily imply *in vivo* effectiveness.

For a Brief Summary of Prescribing Information, please see following page.

MSD
MERCK SHARP & DOHME

It's got to be Mefoxin® IV/IM

(Cefoxitin Sodium | MSD)

Indications and Usage: *Treatment*—Serious infections caused by susceptible strains of the designated microorganisms in the following diseases:
LOWER RESPIRATORY TRACT INFECTIONS, including pneumonia and lung abscess, caused by *Streptococcus pneumoniae*, other streptococci (excluding enterococci, e.g., *Strep. faecalis*), *Staphylococcus aureus* (penicillinase and non-penicillinase producing), *Escherichia coli*, *Klebsiella* species, *Hemophilus influenzae*, and *Bacteroides* species.
GENITOURINARY INFECTIONS. Urinary tract infections caused by *E. coli*, *Klebsiella* species, *Proteus mirabilis*, indole-positive *Proteus* (which include the organisms now called *Morganella morganii* and *Proteus vulgaris*), and *Providencia* species (including *Providencia rettgeri*). Uncomplicated gonorrhea due to *Neisseria gonorrhoeae* (penicillinase and non-penicillinase producing).
INTRA-ABDOMINAL INFECTIONS, including peritonitis and intra-abdominal abscess, caused by *E. coli*, *Klebsiella* species, *Racteroides* species including the *B. fragilis* group,* and *Clostridium* species.
GYNECOLOGICAL INFECTIONS, including endometritis, pelvic cellulitis, and pelvic inflammatory disease, caused by *E. coli*, *N. gonorrhoeae* (penicillinase and non-penicillinase producing), *Bacteroides* species including the *B. fragilis* group,* *Clostridium* species, *Peptococcus* species, *Peptostreptococcus* species, and group B streptococci.
SEPTICEMIA caused by *Strep. pneumoniae*, *Staph. aureus* (penicillinase and non-penicillinase producing), *E. coli*, *Klebsiella* species, and *Bacteroides* species including the *B. fragilis* group.*
BONE AND JOINT INFECTIONS caused by *Staph. aureus* (penicillinase and non-penicillinase producing).
SKIN AND SKIN STRUCTURE INFECTIONS caused by *Staph. aureus* (penicillinase and non-penicillinase producing), *Staph. epidermidis*, streptococci (excluding enterococci, e.g., *Strep. faecalis*), *E. coli*, *P. mirabilis*, *Klebsiella* species, *Bacteroides* species including the *B. fragilis* group,* *Clostridium* species, *Peptococcus* species, and *Peptostreptococcus* species.
Although appropriate culture and susceptibility studies should be performed, therapy may be started while awaiting these results. Cefoxitin is not active *in vitro* against most strains of *Pseudomonas aeruginosa* and enterococci (e.g., *Strep. faecalis*) and many strains of *Enterobacter cloacae*. Methicillin-resistant staphylococci are almost uniformly resistant to cefoxitin.
Prevention—Prophylactic use in surgical procedures (e.g., hysterectomy, gastrointestinal surgery, cesarean section, transurethral prostatectomy) classified as contaminated or potentially contaminated or in patients in whom subsequent infection at the operative site would present a serious risk, e.g., prosthetic arthroplasty.
MEFOXIN® (Cefoxitin Sodium, MSD) usually should be given ½ to 1 hour before surgery and should usually be stopped within 24 hours since continuing administration of any antibiotic increases the possibility of adverse reactions but, in the majority of surgical procedures, does not reduce the incidence of subsequent infection. However, in patients undergoing prosthetic arthroplasty, it is recommended that MEFOXIN be continued for 72 hours after the surgical procedure. If there are signs of infection, specimens for culture should be obtained for identification of the causative organism so appropriate treatment may be instituted.
Contraindications: Previous hypersensitivity to cefoxitin and the cephalosporin group of antibiotics.
Warnings: BEFORE THERAPY IS INSTITUTED, CAREFUL INQUIRY SHOULD BE MADE TO DETERMINE PREVIOUS HYPERSENSITIVITY REACTIONS TO CEFOXITIN, CEPHALOSPORINS, PENICILLINS, OR OTHER DRUGS. GIVE WITH CAUTION TO PENICILLIN-SENSITIVE PATIENTS. ANTIBIOTICS SHOULD BE ADMINISTERED WITH CAUTION TO ANY PATIENT WHO HAS DEMONSTRATED SOME FORM OF ALLERGY, PARTICULARLY TO DRUGS. IF AN ALLERGIC REACTION TO CEFOXITIN OCCURS, DISCONTINUE THE DRUG. SERIOUS HYPERSENSITIVITY REACTIONS MAY REQUIRE EPINEPHRINE AND OTHER EMERGENCY MEASURES.
Pseudomembranous colitis, from mild to life-threatening in severity, has been reported with virtually all antibiotics (including cephalosporins); therefore, it is important to consider its diagnosis when diarrhea develops in association with antibiotic use. Broad-spectrum antibiotics alter normal flora of colon and may permit overgrowth of clostridia; a toxin produced by *Clostridium difficile* is a primary cause of antibiotic-associated colitis. Mild cases may respond to drug discontinuance alone; in more severe cases, management may include sigmoidoscopy, appropriate bacteriological studies, fluid, electrolyte and protein supplementation, and use of a drug such as oral vancomycin; isolation of the patient may be advisable. Other causes of colitis should also be considered.
Precautions: *General*—Total daily dose should be reduced in patients with reduced urinary output due to renal insufficiency because high and prolonged serum antibiotic concentrations can occur from usual doses. Prescribe with caution in patients with a history of gastrointestinal disease, particularly colitis. Prolonged use may result in overgrowth of nonsusceptible organisms; repeated evaluation of the patient's condition is essential. If superinfection occurs, take appropriate measures.
Drug Interactions—Increased nephrotoxicity has been reported following concomitant administration of cephalosporins and aminoglycoside antibiotics.
Drug/Laboratory Test Interactions—High concentrations (>100 mcg/mL) may interfere with measurement of serum and urine creatinine levels by the Jaffé reaction and produce false increases of modest degree in creatinine levels reported; serum samples should not be analyzed for creatinine if withdrawn within 2 hours of cefoxitin administration. High concentrations may interfere with measurement of urinary 17-hydroxy-corticosteroids by the Porter-Silber reaction and produce false increases of modest degree in levels reported. A false-positive reaction for glucose in urine has been observed with CLINITEST** reagent tablets.
Carcinogenesis, Mutagenesis, Fertility Impairment—No long-term animal study has been performed on carcinogenic or mutagenic potential. Rat studies at approximately three times maximum recommended human dosage revealed no effects on fertility or mating ability.
Pregnancy Category B—Reproduction studies in rats and mice did not reveal teratogenic or fetal toxic effects, although fetal weights were slightly decreased. In rabbits, cefoxitin was associated with a high incidence of abortion and maternal death, neither considered teratogenic. There are, however, no adequate and well-controlled studies in pregnant women. Because animal reproduction studies are not always predictive of human response, this drug should be used during pregnancy only if clearly needed.
Nursing Mothers—Excreted in human milk: Exercise caution.
Pediatric Use—Safety and efficacy in infants from birth to three months have not yet been established. In children three months and older, higher doses have been associated with increased incidence of eosinophilia and elevated SGOT.
Adverse Reactions: The most common adverse reactions have been local reactions following intravenous or intramuscular injection. Other adverse reactions have been encountered infrequently. *Local Reactions*—Thrombophlebitis with intravenous administration; pain, induration, and tenderness after intramuscular injections. *Allergic Reactions*—Rash (including exfoliative dermatitis), pruritus, eosinophilia, fever, and other allergic reactions including anaphylaxis. *Cardiovascular*—Hypotension.
Gastrointestinal—Diarrhea, including documented pseudomembranous colitis during or after treatment, and, rarely, nausea and vomiting. *Blood*—Eosinophilia, leukopenia including granulocytopenia, neutropenia, anemia, including hemolytic anemia, thrombocytopenia, and bone marrow depression. A positive direct Coombs test may develop in some individuals, especially those with azotemia. *Liver Function*—Transient elevations in SGOT, SGPT, serum LDH, and serum alkaline phosphatase; jaundice. *Renal Function*—Elevations in serum creatinine and/or blood urea nitrogen levels and, rarely, acute renal failure.
Note: In group A beta-hemolytic streptococcal infections, therapy should be maintained for at least 10 days to guard against the risk of rheumatic fever or glomerulonephritis. In staphylococcal and other infections involving a collection of pus, surgical drainage should be carried out where indicated. Intramuscular injections should be well within the body of a relatively large muscle such as the upper outer quadrant of the buttock (i.e., gluteus maximus); aspiration is necessary to avoid inadvertent injection into a blood vessel. The total daily dosage in infants and children should not exceed 12 grams.
How Supplied: Sterile cefoxitin sodium in vials, infusion bottles, and ADD-Vantage®† vials containing 1 gram or 2 grams cefoxitin equivalent and in 10-gram bulk bottles.

* *B. fragilis*, *B. distasonis*, *B. ovatus*, *B. thetaiotaomicron*, *B. vulgatus*

Natural Killer Sensitivity of Colorectal Carcinoma Targets

Correlation With Degree of Differentiation

Darius J. Bägli, MD, CM; Glenn D. Steele, Jr, MD, PhD; Teresa Barlozzari, PhD

• Lymphocytes with natural killer (NK) ability recognize a wide range of target cells; however, the mediators of specific target recognition are still largely unknown. Despite the diversity of the NK target repertoire, it is typified by cells of relatively immature phenotype. The purpose of this study was to determine if colorectal carcinoma (CRC) targets were sensitive to spontaneous lysis by fresh human NK effector cells and to observe the role of CRC differentiation in this process. Results demonstrated that poorly differentiated CRC targets were susceptible to NK-mediated lysis whereas CRC targets with more differentiated structure were NK resistant. In addition, chemical induction of a more mature CRC phenotype confers NK resistance on a previously NK-susceptible target. This maturation-related modulation of NK sensitivity can provide a model with which to further study interaction between NK cells and CRC targets.

(*Arch Surg* 1989;124:89-93)

Lymphocytes possessing natural killer (NK) activity are unique in their ability to spontaneously lyse a wide range of normal, infected, or malignant and metastatic cell targets.[1] However, the structures mediating specific target recognition are still largely unknown, both for the NK cells and the targets themselves. Immunochemical techniques have demonstrated the importance of some molecules involved in NK activity. These include the glycoprotein LFA-1, a surface component of many different leukocytes involved in cell-cell adhesion. Monoclonal antibodies directed against LFA-1 on the surface of NK and cytotoxic T lymphocytes have been shown to abrogate the cytotoxic potential of these effector cells.[2] In humans and animals, molecules functionally related to the extracellular matrix glycoprotein laminin have been linked to processes of NK target recognition.[3-5] The implication of both these structures can be reconciled with their principal role as adhesion molecules, since the formation of a stable conjugate between the NK cell and its target is the first requirement for natural killing.[6] In addition, monoclonal antibodies against the T-200 glycoproteins[7] and GM_1 glycolipids have similarly implicated these molecules in NK function.

Despite the variety of NK-susceptible target cells and the heterogeneity of the molecules possibly involved in their recognition by NK cells, they do possess certain features in common. These include rapid growth and relatively immature phenotypes.[1,8] Indeed, these features are typical of tumor cells. However, they also describe some otherwise normal cells that constitute NK targets, such as immature thymocytes and bone marrow cells.[9] It is the NK susceptibility of these latter immature cells that has suggested a role for NK cells in regulating some hematopoietic processes in vivo.[10] On maturation, the NK susceptibility associated with human myeloid and lymphoid precursors is lost.[9] Similarly, in a study of murine teratoma, clones representing later stages of development with relative lack of embryonal surface antigens were virtually resistant to NK cytolysis.[11]

Developing this concept further, attempts to induce maturation of NK targets by chemical agents have met with successes. The well-studied NK target K-562 (a human erythroleukemia), when treated with the potent differentiating agent sodium butyrate, resulted in the induction of a number of differentiation markers. In addition, a striking resistance to NK lysis[12] was observed. Similar findings have been reported for other NK targets such as the human histiocytic lymphoma line U-937 treated with tetradecanoyl phorbol acetate, and the murine erythroid stem line GM-86 treated with hexametabisacetamide.[13] In both cases, significant native NK susceptibility was abrogated after treatment with unrelated agents that induced changes associated with a more mature phenotype.

In the case of solid tumors as well, chemical agents have been successfully employed to induce maturation. Agents such as sodium butyrate, tretinoin (retinoic acid), and polar solvents (dimethyl sulfoxide and dimethylformamide) have been used to differentiate murine melanoma,[14] mammary and rhabdomyosarcoma,[15] and human colorectal carcinoma (CRC) cell lines.[16-19] As a group, however, solid tumors have generally proved to be poor targets for natural unstimulated cytotoxicity.[20] The NK potential inherent in normal peripheral blood lymphocytes (PBLs) becomes significant against solid tumors only in the presence of interleukin 2.[21] Furthermore, little information about the relationship between the preexisting or induced maturational state of solid tumors and NK susceptibility is available.

The goals of the present study were to establish whether human CRC could act as targets for the spontaneous NK effectors, and whether the stage of CRC differentiation could influence their susceptibility to NK-mediated lysis. Results showed that the three CRC targets representing poor or early states of differentiation were sensitive to NK lysis, whereas the three CRC targets representing better or more mature stages of differentiation were insensitive to lysis by NK cells. Furthermore, the significant NK susceptibility of the poorly differentiated CRC targets

could be virtually eliminated after treatment of the targets with a chemical differentiating agent.

METHODS

Cell Lines

Colorectal carcinoma cell lines clone-A, MIP-101, CCL-227, CCL-235, CX-1, CCL-230, and the human erythroleukemia line K-562 were maintained in RPMI-1640 medium (GIBCO, Grand Island, NY) supplemented with 10% heat-inactivated fetal calf serum (Hazelton, Dutchland, Penn), 100 U/mL of penicillin (GIBCO), and 2 mmol/L of L-glutamine (GIBCO) referred to as "culture medium." Cells were passaged three times per week. All lines were tested free of mycoplasma by the Hoechst stain (Sigma Chemical Co, St Louis) for mycoplasmal RNA.

Preparation of PBLs and Large Granular Lymphocytes (LGLs)

Fresh human PBLs were obtained from the peripheral blood of healthy donors by Ficoll-Hypaque sedimentation. Cells were washed with Hanks' balanced salt solution (GIBCO) and monocyte/macrophage populations were removed by adherence on glass flasks. After passage through nylon wool columns, the nonadherent cells were fractionated by centrifugation on discontinuous gradients of an inert silica compound (Percoll, Pharmacia, Uppsala, Sweden) as described elsewhere.[22] Briefly, seven different fractions of Percoll (40.8%, 43%, 45.8%, 48.3%, 50.8%, 53.3%, and 66.6% in culture medium) were prepared. Lymphocytes harvested from the second and third low-density layers were pooled and used as LGLs throughout. The LGL structure was confirmed by Giemsa staining (Fischer).

Chemical Treatment With Differentiating Agent

The MIP-101 and clone-A cells were grown in culture medium in the presence or absence of 2 mmol/L of sodium butyrate (Sigma) for 14 days prior to placing in cytotoxicity assays. Cell viability for both the treated and untreated cells was assessed to be greater than 90% by trypan blue exclusion.

Cytotoxicity Assays

Target cells, 5×10^6, harvested by rubber policeman, were labeled with 300 μCi of sodium labeled with chromium 51 tetraoxide ($Na^{51}CrO_4$) (New England Nuclear, Boston) for 45 minutes at 37°C in medium with 5% fetal calf serum. Cells were washed twice, allowed to sit for 30 minutes at room temperature to reduce final spontaneous release, and washed again. Then 100 μL to labeled target cells per well at a concentration of 1×10^5/mL was plated in quadruplicate in 96-well, round-bottom, tissue culture plates (Costar); 100 μL of effectors was plated at effector-target (E/T) ratios of 40:1, 20:1, and 10:1. Plates were incubated for four hours at 37°C in 5% carbon dioxide/95% oxygen. Then 100 μL per well was harvested and counted. Spontaneous release and total release were determined by adding 100 μL of medium or 6 mol/L of hydrochloridic acid, respectively, in lieu of effectors, to target cell wells. Spontaneous release did not exceed 15%. Mean specific percent cytotoxicity was determined by the following formula:

$$\text{Cytotoxicity} = \{[(\text{Experimental cpm} - \text{Spontaneous Release cpm})]/[(\text{Total Release cpm} - \text{Spontaneous Release})]\} \times 100.$$

Any target showing significant improvement in lysis (>15% cytotoxicity) with LGL as effectors was interpreted as being an NK-susceptible target.

Statistical Analysis

Data were analyzed using the Student t test.

RESULTS

PBL Cytotoxicity

Peripheral blood lymphocytes were tested for cytotoxicity against six different CRC cell lines (Fig 1). The human erythroleukemia cell line K-562, the classic target for NK cytotoxicity, was used as the control. The six CRC targets consisted of three poorly differentiated lines (clone-A, MIP-101, CCL-227) and three well-differentiated lines (CCL-235, CX-1, CCL-230). With fresh human PBLs, only the control line, K-562, was significantly killed (35% at an E/T ratio of 40:1 [Fig 1]). Even with an E/T ratio of 40:1, only low-level (<15%) cytotoxicity was seen for the CRC targets. However, all six targets showed significant cytotoxicity when PBL effectors were first stimulated with Hr–interleukin 2 (data not shown).

Effect of Enrichment for NK Activity on CRC Target Lysis (PBLs vs LGLs)

To test whether CRC could truly act as natural targets, as was suggested above by the small degree of lysis achieved with fresh unstimulated PBLs, LGLs were employed as effectors in cytotoxicity assays along with PBLs. The NK activity within the PBL population is known to exist predominantly in the subpopulation of LGLs. The effect of PBL enrichment for LGLs was demonstrated first in cytotoxicity assays against K-562, the classic NK target (Fig 2). Most of the NK activity was harvested as LGLs from the Percoll fractions of 43% and 45.8%, representing the second and third layers of the discontinuous Percoll gradients employed (Fig 2). This represents a significant improvement in cytotoxicity (PBLs alone, 16%; LGL fractions 2 and 3, 45% [Fig 3]). When PBLs and LGLs from the same donor were compared for their cytotoxic ability against the six CRC targets, an interesting stratification

Fig 3.—Lysis of colorectal carcinoma by large granular lymphocytes (LGLs) and peripheral blood lymphocytes (PBLs). Effector-target ratio is 40:1. Peripheral blood lymphocytes and large granular lymphocytes (natural killer–enriched cells) were obtained from same donor for any single target cell line. Similar results were obtained for effector-target ratios of 20:1 and 10:1. Results (±SD) are representative of four assays in quadruplicate. Striped bars indicate percent of cytotoxicity by PBLs; solid bars, percent of cytotoxicity by LGLs (for poorly differentiated targets: PBLs vs LGLs, $P<.005$).

Fig 4.—Normal and sodium butyrate–treated MIP-101 and clone-A colorectal carcinoma. Top left, MIP-101; bottom left, clone-A; top right, MIP-101 after 14 day's culture in 2 mmol/L of sodium butyrate; bottom right, clone-A after 14 days' culture in 2 mmol/L of sodium butyrate (periodic acid–Schiff, ×250).

Fig 5.—Effect of sodium butyrate treatment on poorly differentiated colorectal carcinoma susceptibility to natural cytotoxicity; colorectal carcinoma cultures were supplemented with 2 mmol/L of sodium butyrate for 14 days, washed, and used in cytotoxicity assays. Effector-target ratio is 40:1. Similar results were obtained for effector-target ratios of 20:1 and 10:1. Results (±SD) are representative of four experiments in quadruplicate. Striped bars indicate percent of cytotoxicity by peripheral blood lymphocytes; solid bars, percent of cytotoxicity by large granular lymphocytes (for large granular lymphocytes, control vs sodium butyrate treatment, $P<.005$).

Fig 6.—Reversibility of sodium butyrate–induced natural killer resistance of poorly differentiated colorectal carcinoma treated with 2 mmol/L of sodium butyrate were grown in sodium butyrate–free medium for 14 days prior to use as targets in cytotoxicity assays. Effector-target ratio is 40:1. Similar results were obtained for effector-target ratios of 20:1 and 10:1. Solid bars indicate percent of cytotoxicity by large granular lymphocytes (large granular lymphocytes, control or reverted vs sodium butyrate treatment, $P<.005$).

was observed (Fig 3). Against all three poorly differentiated targets, the enrichment for NK activity produced LGL cytotoxicities that were significant. In contrast, none of the better differentiated targets showed any significant improvement in cytotoxicity with the use of LGLs as effectors, thus revealing them to be NK-resistant targets. These data suggest that an inverse relationship exists between the state of differentiation of CRC targets and their susceptibility to NK-mediated lysis by effector lymphocytes.

Effect of Chemically Induced Differentiation on NK Cytotoxicity

The following experiments determined whether the relationship between NK susceptibility and differentiation state of the targets observed could be preserved and demonstrated with targets in two different states of differentiation. The poorly differentiated targets MIP-101 and clone-A were treated with sodium butyrate, which is recognized as a potent inducer of differentiation in many cellular systems. After 14 days of treatment with 2 mmol/L of sodium butyrate, MIP-101 and clone-A cells underwent a number of characteristic maturational changes in growth rate, morphology, and metabolism (Fig 4 and "Comment" section). Also, sodium butyrate did not affect cell viability as confirmed by trypan blue exclusion. Both untreated and sodium butyrate–treated MIP-101 and clone-A cells were subjected to cytotoxicity assays with PBLs and LGLs (Fig 5). Neither the untreated nor the treated targets showed any significant cytotoxicity with PBLs as effectors. With LGLs as effectors, both untreated targets showed significant lysis as described earlier. After sodium butyrate treatment of the targets cells, however, no significant NK cytotoxicity remained for either target with LGLs as effectors (Fig 5). The pattern of killing of MIP-101 and clone-A cells after chemical differentiation by sodium butyrate now paralleled that of the well-differentiated lines described above. After culture of the sodium

butyrate–treated targets in sodium butyrate–free culture medium for 14 days, they resume their original morphology, and NK susceptibility returns to significant levels (Fig 6). These data show that the apparent resistance to NK-mediated cytotoxicity associated with CRC targets of a more differentiated phenotype can be conferred on a previously poorly differentiated CRC target with high NK susceptibility by chemically inducing the target to a more mature morphologic state. In addition, this resistance effect is reversible.

COMMENT

We have demonstrated that an inverse relationship exists between the state of differentiation of CRC targets and their susceptibility to NK lysis. Poorly differentiated CRC showed marked susceptibility to NK cell-mediated lysis, whereas the well-differentiated CRC targets were NK resistant. Furthermore, the chemical induction of a more mature phenotype in two of these CRC also induces a resistance to NK cytolysis, implying that NK susceptibility is truly dependent on the phenotype of the target.

These observations are consistent with previous findings that have demonstrated that NK susceptibility is significantly influenced by the relative phenotype of the target. Murine thymocytes from very young animals (5 days old) showed maximal NK sensitivity in standard cytolytic assays. This sensitivity fell directly with increasing age until, at 7 months, thymocytes were virtually resistant to NK cytolysis.[13] The murine embryonal carcinoma–derived teratoma Nulli-SCC.1 is a highly NK-sensitive target with cytolytic potential approaching that of the classic murine NK target, YAC.[11] However, more differentiated endodermal strains derived from the same 129 teratoma lose NK susceptibility. Similarly, we observed marked NK-mediated cytolysis with poorly differentiated CRC targets. The three susceptible poorly differentiated lines share the known morphologic features of small spherical cells with some flattened cells, rapid growth rate, and trace (CCL-227) or no carcinoembryonic antigen (CEA) production. All three well-differentiated lines tested showed slower growth rates, recognized morphologic characteristics typified by flattened cells in close approximation to one another in monolayer cultures, and marked CEA production. These well-differentiated targets proved resistant to NK lysis.

This differentiation-related NK susceptibility was further analyzed by controlled differentiation of poorly differentiated NK-susceptible targets. When treated with sodium butyrate, the human NK target K-562 undergoes several maturational changes. K-562 is a leukemic stem line expressing few embryonic and fetal markers.[12] Culture in sodium butyrate increases endogenous peroxidaselike activity, slows growth rate, and significantly (50%) decreases NK-mediated lysis. The NK resistance was dose dependent and reversible. In addition, several K-562 subclones were also protected from NK lysis after sodium butyrate treatment, thus demonstrating that the differentiation-related changes in NK sensitivity were not an aberrant response of any single subclone.[12] Sodium butyrate treatment of the poorly differentiated CRC targets MIP-101 and clone-A produced similar results. Maturational changes included a decrease in growth rate, increase in cell size accompanied by increasingly fibroblastoid morphology and formation of mucin-containing vacuoles evidenced by periodic acid–Schiff staining. While neither target is a constitutive producer of CEA, this marker became detectable in culture medium after one to two weeks of sodium butyrate treatment (data not shown). When tested after two weeks of sodium butyrate treatment, NK sensitivity for both MIP-101 and clone-A was virtually lost. Similar NK resistance occurred as early as one week into treatment. Removal of sodium butyrate led to complete reversal of the differentiating morphologic and biochemical changes observed.

Coincident with this reversal was the return of NK sensitivity. In the context of natural killing, the ability to revert to original phenotype on withdrawal of a maturational agent[17,23] suggests that NK recognition structures are modulated on target surfaces during differentiation and that this modulation can be induced in vitro.

To our knowledge, the mechanism by which altered states of differentiation influence NK susceptibility is still unknown. However, any such mechanism must reasonably involve NK recognition molecules on the target cell surface. Sialic acid may be one such molecule involved in NK target recognition. Neuraminidase-accessible cell surface sialic acid shows an inverse correlation with NK sensitivity in sodium butyrate–differentiated K-562 cells.[24] Similar NK resistance correlating with increased sialic acid has been reported after interferon treatment of several murine cell targets.[25,26]

Chemical differentiation by sodium butyrate is known to affect cellular, membrane-associated,[16] and secreted[23] CEA levels. Surface CEA levels have been positively correlated with NK susceptibility in human carcinoma.[27] However, all three well-differentiated CRC in this study are CEA producers and were NK resistant. Furthermore, whether the trace CEA secreted by the butyrate-induced CRC cell line targets was involved in their NK resistance remains to be determined.

The involvement of major histocompatibility complex antigens in NK activity has recently been suggested.[28-30] These antigens are markers of cellular differentiation. In this study, the native clone-A target showed no expression of HLA-DR antigen while the sodium butyrate–treated clone-A targets showed a small increase in HLA-DR expression (data not shown). Whether this increase was directly associated with the NK resistance observed is unknown.

Finally, transfection techniques employing transforming oncogenes have demonstrated that NK cells are able to recognize and kill previously NK-resistant murine or rat fibroblasts that have been transformed to the malignant phenotype by c-Ha-*ras*[31] or v-Ki-*ras*,[32] respectively. Whether oncogene-associated NK sensitivity plays any role in the differentiation-related NK susceptibilities seen in this study remains to be determined. Investigation of a role for an activated or mutated *ras*-p21 protein product in this context would be of great interest.

In summary, we have shown that the NK susceptibility of CRC targets is dependent on the CRC state of differentiation. These observations are reconciled by similar descriptions in other tumor systems. Furthermore, the chemical differentiation of CRC targets to a more mature phenotype confers on them the NK resistance shared by well-differentiated CRC. As understanding of the NK target repertoire increases, the ability to induce reversible maturation-related alterations in NK sensitivity in this disease can provide a controlled model with which to study the processes that mediate interaction between NK cells and CRC.

This investigation was supported in part by grants P01 CA 44704-01 and CA-09280 from the National Institutes of Health, Bethesda, Md (Dr Bägli).

The authors wish to thank Barbara Wolf, MD, for assistance with the pathology review of the cell preparations.

Discussion

Q Did you look at cell cycle distributions of your killer cells and of your well-differentiated and poorly differentiated tumor cells? In other words, could it be that your T cells in S phase are competing for a substrate and they die because they cannot?

A Yes, I see what you mean. We did not specifically look at the effect of cell cycle on the efficacy of killing by these cells, but in other tumor systems where sodium butyrate has been used to differentiate targets, particularly the classic NK target K-562, it was shown that the rate of growth, log phase vs plateau, did not affect the resistance that was conferred.

Q As everyone knows, in the NK lymphokine-activated killer area there are probably gradation effects, both quantitatively and qualitatively, of first the binding and then the killing event. Probably many of the functions we ascribe to lymphokine-activated killer cells are activated NK cells that are able to cross histocompatibility barriers to kill targets between different individuals or cells with different histologic types.

My question is: In comparing the cells that are poorly differentiated with those that are well differentiated, could part of the difference be related to the fragility of the poorly differentiated cells? I wonder if you saw some differences in the background lyses between these two groups of cells that may hint at least that those that are poorly differentiated may be more susceptible to lysis with less of a cytotoxic effect or less binding avidity of the cytotoxic cell. Have you tried these experiments with different doses of interleukin 2? Because, if this is simply a quantitative difference of receptor expression on the target that allows NK cells to bond to the more fragile cells, then you may be able to override that by preincubating the NK cells with interleukin 2 and see some degree of killing with the well-differentiated cells as well.

A In answer to the first question, we did not carry out specific studies measuring osmotic fragility of the targets. However, in terms of viabilities throughout the course of the experimental procedure, the ability to be labeled, the background spontaneous release of chromium, all of which indirectly speak to fragility, no differences were seen between the well-differentiated and poorly differentiated targets. Similarly, when the poorly differentiated targets were induced to differentiate chemically with sodium butyrate, they handled well and their viability was very good. With respect to interleukin 2, early on we did interleukin 2 activation in the experimental setup, both with the nonenriched PBL preparation as well as the LGLs, and in that case we did see significant lyses appearing for the well-differentiated targets. The poorly differentiated target lyses were even higher than the ones we saw herein. So certainly activation of these NK cells can render them more sensitive to a lower concentration of receptor on the surface of the target, as you mentioned.

Q It would appear paradoxic that if NK cells do have an in vivo role, then the cells that we would consider more of a problem, the poorly differentiated cells, would appear more susceptible to NK killing. Since we know that culture cells undergo a tremendous number of changes with time, have you looked at fresh tumor targets to see whether, in fact, these results are obtained in the natural situation?

A We have not looked at fresh tumor targets. That is an area that we would like to get into with this system. With respect to the apparent discrepancy between what is seen in terms of clinical prognosis with well-differentiated and poorly differentiated cells, it may be taking a great leap of faith to expect what is seen here to exactly mimic the clinical situation. However, you can see a parallel between these results and the incidence of the state of differentiation in pathologic specimens. The great minority of tumors are poorly differentiated, and this might be expected if you allow NK cells a role in early immune surveillance. The data that we showed today may parallel such a situation.

Cachectin Activity in the Serum of Cachectic, Tumor-Bearing Rats

Mark C. Stovroff, MD; Douglas L. Fraker, MD; Jeffrey A. Norton, MD

• Cachectin/tumor necrosis factor has been postulated to be a possible mediator of cancer cachexia. Using a sensitive bioassay, we attempted to detect circulating cachectin activity in the serum of sarcoma-bearing rats and to correlate levels with measurements of cachexia and the extent of disease. In addition, we resected the tumor to determine the time course of reversal of cachexia and the disappearance of cachectin activity in the serum. Circulating cachectin activity was not detectable in the serum of non–tumor-bearing rats or in tumor-bearing rats until 28 days after implantation. With evidence of food intake and body weight decline, cachectin activity became detectable in the serum and levels increased as cachexia and tumor burden increased. Serum cachectin activity levels correlated directly with tumor burden and inversely with food intake and body weight change. After resection of the tumor, food intake and body weight increased and serum cachectin activity became undetectable. Serum triglyceride levels were higher in cachectic tumor-bearing rats than in pair-fed non–tumor-bearing controls, and levels decreased after tumor resection as cachectin activity decreased. The results suggest that cachectin is a humoral mediator of cachexia in this rat-tumor model.

(*Arch Surg* 1989;124:94-99)

Cancer cachexia is a complex syndrome that includes anorexia and host tissue wasting. It is one of the most common manifestations of neoplasia and one that impacts negatively on the duration and quality of life of the cancer-bearing host.[1] Its cause is unknown, but is postulated to be a currently unidentified humoral factor.[2] Previous studies have demonstrated that the anorexia and cachexia of rats bearing a sarcoma was transferable via the circulation across a parabiotic anastomosis.[3]

Cachectin/tumor necrosis factor (TNF) may be a mediator of the cachexia associated with malignant neoplasms.[4] Initially isolated in the serum of trypanosomiasis-affected rabbits suffering paradoxically from both a profound hyperlipidemia and a wasting diathesis, cachectin was found to suppress the activity of lipoprotein lipase, a key enzyme in lipid biosynthesis.[5] Further studies have indicated that cachectin is a mediator of the metabolic derangements of chronic and acute infection.[4,6] The appearance of animals with chronic infectious diseases and cancer is similar, suggesting that cachectin may have a role in the pathophysiology of cancer cachexia as well. The results of studies to detect its presence in the serum of patients with cancer have been contradictory. Despite sensitive biologic and immunologic assays, studies by Scuderi et al[7] and Waage et al[8] failed to detect circulating cachectin/TNF levels in the serum of patients with cancer. More recently, Balkwill et al[9] were able to measure circulating levels of cachectin/TNF in the serum of some patients with cancer, but found no correlation between serum levels and clinical measures of cachexia.

In the present investigation, we attempted to detect circulating cachectin activity in the serum of sarcoma-bearing rats and to correlate levels with measurements of cachexia and extent of disease. In addition, we resected the tumor to determine the time course of reversal of cachexia and the disappearance of cachectin activity from the serum. The results suggest that cachectin is a humoral mediator of cachexia in this experimental rat-tumor model.

MATERIALS AND METHODS

General

The experiments were performed on male Fischer 344 rats initially weighing between 200 and 250 g. Animals were individually housed in wire-bottomed cages within a temperature- and humidity-controlled room. A 12-hour light/dark cycle was maintained. Rats were fed a casein-based semisynthetic diet (C-21, ICN, Cleveland) that allows accurate measurement of daily intake.[10]

The tumor was a transplantable methylcholanthrene-induced sarcoma. The tumor was transplanted in the subcutaneous space by either a sterile, viable, single-cell suspension (10^6 cells) or placement of 2-mm viable tumor fragments with the animal under intraperitoneal pentobarbital sodium (35 mg/kg) anesthesia. The sarcoma grows uniformly and the natural history has been previously reported.[11] It is locally invasive, does not metastasize, and causes anorexia and weight loss by 24 days after implantation. Death occurs from 30 to 40 days after transplantation.

The tumor was measured, using calipers, in three orthogonal linear dimensions three times weekly from the time it was first

palpable. At death, total body weight was recorded and the tumor was dissected free and weighed.

Blood Drawing

Fasting animals were anesthetized with intraperitoneal pentobarbital sodium (35 mg/kg); blood was collected in experiment 2 by aortic cannulation and in other experiments by retro-orbital puncture. Blood was allowed to clot at 4°C for two hours and serum was separated by centrifugation. Serum in experiment 2 underwent further separation via membrane filtration to isolate molecules of a molecular weight between 10 and 30 kilodaltons. Serum was then assayed immediately or frozen at −70°C until analyzed.

Tumor Resection

Tumor-bearing rats were anesthetized with intraperitoneal pentobarbital sodium (30 mg/kg) and the tumor was separated from the flank using blunt and sharp dissection. After all bleeding was controlled, the skin was reapproximated with clips. All non–tumor-bearing rats underwent similar anesthesia and a sham operation in which the skin was incised, a deep subfascial pocket was made, and skin was reapproximated.

L929 Bioassay

A standard cytotoxicity assay for cachectin/TNF activity using a TNF-sensitive L929 cell line was performed.[12] One hundred microliters of a suspension containing 2.5×10^5 cells/mL of L929 cells in RPMI 1640 medium supplemented with 10% fetal calf serum was plated on 96-well culture plates (Costar, Cambridge, Mass) and incubated overnight to establish a confluent monolayer. On parallel plates, serial dilutions of serum samples were made in complete medium with 2 mg/L of dactinomycin (Merck, Sharpe and Dohme, West Point, Pa) and 100-μL aliquots were transferred to the wells containing the L929 cells, giving a final concentration of 1 mg/L of dactinomycin. In addition, L929 cells incubated with dactinomycin-containing medium served as a control for cell viability. After an 18-hour incubation at 37°C the surviving cells were fixed and stained wtih 5% crystal violet (Sigma Chemical Co, St Louis). The dye uptake of each well was then determined by a titertak (Flow Laboratories, Helsinki) at 590 nm. One unit of activity was defined as the reciprocal of the dilution required to produce a 50% decrease in absorbance relative to control cells exposed to dactinomycin alone. Each sample was assayed in triplicate. In parallel assays employing a neutralizing antibody, samples were mixed with a 1:1 solution of a 1:25 dilution of a polyvalent TNF antibody (Endogen, Boston) for one hour at 4°C before the addition of the L929 cells. Each assay included an internal standard for reference using human recombinant TNF (Cetus, Emeryville, Calif).

Statistics

Data are presented as the mean ± SEM. Parametric results are analyzed by Student's independent *t* test and nonparametric results are analyzed by Wilcoxon's rank sum test. Percents are compared by Fisher's exact test.

Experiment 1

To verify the L929 cytotoxicity assay and the method of the collection and handling of serum specimens, cachectin activity was measured in the serum of nine F344 male rats before and after an intravenous, 200-μg/kg injection of recombinant human TNF. Serum was collected at 0, 30, 60, and 120 minutes, and was analyzed by the L929 bioassay.

Experiment 2

Experiment 2 was designed to determine the detectability of circulating cachectin activity in the serum of tumor-bearing rats. Fifty F344 male rats were acclimated to the C-21 diet and to individual cages. They were then randomized by a random-number method to receive either 5×10^6 viable sarcoma cells subcutaneously (n = 40) or saline solution (n = 10). Two rats did not develop tumor and were excluded from analysis. Food intake, body weight, and tumor size were measured daily. At weekly intervals after tumor implantation (beginning on day 14 when tumor became palpable) animals in a random group of tumor-bearing and non–tumor-bearing rats were killed and serum was collected. Cachectin activity was determined using the L929 bioassay. At death tumor weight, body weight, and tumor burden (tumor weight/total body weight) were recorded for each rat.

Experiment 3

Seventy F344 male rats were acclimated to the C-21 diet and to individual cages. Forty tumor-bearing rats (28 days after implantation) underwent tumor resection when food intake in each animal was noted to have declined to less than 15% of normal rat food intake (<2 g/d). Thirty non–tumor-bearing rats were randomized to receive either normal food intake (ad libitum) or were paired to the tumor-bearing rats' food intake and each rat subsequently underwent a similar sham operation. Before and after resection, fasting-stage serum was collected and assayed for cachectin activity and triglyceride levels. Triglycerides were analyzed on an automated instrument (ABA 100, Abbott Laboratories, South Pasadena, Calif) by a spectrophotometric method. After resection, the survival, daily weight, and food intake were recorded.

RESULTS

Experiment 1

Recombinant human TNF given intravenously results in peak levels of detectable serum cachectin activity at 30 minutes, but high levels are still detectable at 120 minutes (Fig 1). Clearance of serum cachectin activity is rapid, with a half-life of less than 30 minutes. These results demonstrate that the L929 method that we used can reliably detect cachectin levels within the circulation.

Experiment 2

Food intake of non–tumor-bearing rats remained constant throughout the experimental period (15 g/d) (Table 1). The food intake of tumor-bearing rats remained constant until day 21, when it first declined significantly (Table 1 and Fig 2). From day 21 onward, the food intake of tumor-bearing rats progressively declined as the tumor burden progressively increased.

Circulating cachectin activity was not detectable in the serum of non–tumor-bearing rats or tumor-bearing rats at 21 days after implantation (Table 1). At 28 days after tumor implantation, cachectin activity was detectable in the serum of tumor-bearing rats (Fig 2 and Table 1) who were eating only 3 g/d and were losing weight (Table 1). With a greater tumor burden and further decline in food intake and body weight, cachectin activity levels became detectable in the serum of a greater proportion of tumor-bearing rats (Fig 2) and levels continued to increase significantly (Fig 2 and Table 1).

Serum cachectin activity levels correlated directly with tumor burden ($r = .72$; $P < .001$; Fig 3). Serum cachectin activity levels correlated inversely with food intake ($r = -.66$; $P < .001$; Fig 4) and body weight change ($r = -.75$; $P < .001$; Fig 5). These results correlated tumor-bearing serum cachectin activity levels with three important measures of cachexia: tumor burden, food intake, and body weight.

Experiment 3

Before tumor resection, tumor-bearing rats ate significantly less than non–tumor-bearing rats ($P < .005$). After tumor resection, tumor-bearing rats gradually increased their food intake and, by postoperative day 7, they were eating an amount similar to that of non–tumor-bearing rats (Fig 6). Non–tumor-bearing rats had a significant decline in food intake only on their operative and first postoperative days ($P < .01$), and their intake then returned quickly to baseline levels (Fig 6).

Fig 1.—Serum cachectin activity levels after intravenous injection of 200 μg/kg of recombinant human tumor necrosis factor. Activity levels were undetectable at time 0 before injection, were highest at 30 minutes, and decreased as time increased, indicating that sample collection methods and L929 assay could reliably detect serum cachectin activity levels.

Opposite to the increase in food intake of tumor-bearing rats after tumor resection were the level and presence of cachectin activity in the serum (Fig 7 and Table 2). Before tumor resection, 50% of the 28-day tumor-bearing rats assayed had detectable cachectin activity in the serum, with mean levels of 92±25 U/mL, vs consistently undetectable levels in non–tumor-bearing rats ($P<.01$). The level of cachectin activity in the serum of tumor-bearing rats before and soon after resection was not significantly different (Fig 7 and Table 2). However, by day 7 after tumor resection, when food intake returned to levels similar to those in non–tumor-bearing rats, cachectin activity was no longer detectable in the serum. In addition, low food intake itself did not cause cachectin activity in the serum because no pair-fed, non–tumor-bearing rat had detectable cachectin activity (Table 2).

Before tumor resection, tumor-bearing rats had significantly higher serum triglyceride levels than either non–tumor-bearing rats with normal food intake or non–tumor-bearing rats pair-fed to tumor-bearing rat food intake ($P<.005$) (Table 3). Following tumor resection, tumor-bearing rats' serum triglyceride levels decreased, and by postoperative day 7 these levels were significantly less than in either control group ($P<.005$). Pair-fed non–tumor-bearing rats exhibited a reverse pattern. Before sham operation and when consuming reduced levels of food, serum triglyceride levels of pair-fed non–tumor-bearing rats were significantly lower than levels in either the ad libitum–fed non–tumor-bearing rats or the tumor-bearing rats ($P<.005$). Postoperatively, as food intake returned to adequate levels, serum triglyceride levels also returned to normal levels. Non–tumor-bearing rats fed ad libitum maintained serum triglyceride levels within the normal range throughout the experiment.

Paralleling the changes in serum triglyceride levels after tumor resection were the changes in serum cachectin activity levels of tumor-bearing rats. Before tumor resection, tumor-bearing rats had high levels of both triglycerides and cachectin activity in the serum (Fig 7). After resection, levels of each substance declined in a similar manner (Fig 7). Serum cachectin activity was not detectable in either control group of non–tumor-bearing rats before or after sham operation.

Table 1.—Mean (±SEM) Food Intake, Body Weight Change, and Cachectin Activity Levels in Non–Tumor- and Tumor-Bearing Rats

Group	Days After Tumor Implant	n	Food Intake, g/d	Body Weight Change, g/wk	Cachectin Activity, U/mL

‡$P<.05$ vs tumor-bearing rats on day 28.

Fig 2.—Food intake, tumor burden, percent with serum cachectin activity detectable, and measured serum cachectin activity level of tumor-bearing rats as time from tumor implant increases. Food intake (closed circles) first significantly declined 21 days after implantation and tumor burden (open circles) of approximately 20%, and progressively declined as tumor burden progressively increased. Cachectin was detectable 28 days after tumor implantation, and levels significantly increased ($P<.05$) and percent of rats with detectable levels increased ($P<.01$) as time from tumor implantation progressed.

COMMENT

Cachectin, or TNF, is a macrophage-secreted peptide that circulates in the bloodstream and acts at distant sites via specific receptors present on a variety of metabolically important tissues such as muscle, adipose tissue, and

Fig 3.—Correlation of serum cachectin activity with tumor burden (tumor weight/total body weight). Serum cachectin activity increased directly with tumor burden ($r = .72$; $P < .001$).

Fig 6.—Food intake of tumor-bearing (closed circles) and non–tumor-bearing (open circles) rats before and after tumor resection or sham operation. Food intake of cachectic tumor-bearing rats progressively declined as non–tumor-bearing rats consumed 15 g/d ($P < .05$). Tumor was resected or sham operation was performed on day 0.

liver.[13] It was recently isolated and purified as a result of two separate lines of research, one to isolate factors that cause the cachexia observed in wasting diseases and the other to isolate factors that cause tumor regression. It is now clear that cachectin is one of the mediators of the tissue and shocklike changes associated with endotoxin, bacteria, and other acute and chronic infectious diseases.[4,5,14] Although cachectin inhibits the synthesis and action of the enzyme lipoprotein lipase,[13,15] reduces body lipid stores,[4] and causes the necrosis of some tumors in animals,[16] investigations aimed at detecting its presence as a possible mediator of the host changes associated with cancer cachexia have been inconsistent. Aderka et al[17] demonstrated cytotoxic activity consistent with TNF activity spontaneously produced in vitro by peripheral blood mononuclear cells from patients with cancer, indicating that endogenous cachectin production may occur as part of the host response to cancer,[17] yet other studies have failed to detect circulating cachectin levels in the serum of tumor-bearing patients.[7,8] Moreover, a recent study using a sensitive enzyme-linked immunosorbent assay detected circulating cachectin levels in serum of some patients with advanced cancer, but levels did not correlate with the extent of disease or other measures of cachexia.[9]

Experimental work in animal models supports the notion that circulating factors cause cancer cachexia and that cachectin may be one of these factors. Previous studies with the sarcoma-bearing Fischer rat have supported the hypothesis that a circulating factor or factors caused the cachexia produced by the tumor. A parabiotic union that had a measured blood flow of 1.5% of the cardiac output per minute was able to transmit cachexia (anorexia and host weight loss) from a tumor-bearing rat to a non–tumor-bearing rat. Since the two rats were coupled only by the bloodstream and no tumor was present in the non–tumor-bearing animal at necropsy, it appeared likely that a stable circulating factor crossed the anastomosis and produced cachexia.[3] Recent work has indicated that non–tumor-bearing rats become tolerant to the anorectic and cachectic effects of recombinant human cachectin after repeated administration.[14,18] When tolerant non–tumor-bearing rats were given an inoculation of sarcoma, they lived substantially longer than animals previously unexposed to cachectin. Tumor growth was identical in cachectin-tolerant and

control rats, but features of cachexia, including declining food intake and weight loss, were improved in cachectin-tolerant rats.[18] This observation was consistent with the hypothesis that cachectin caused cachexia in this experimental tumor model, since tolerance to cachectin offered protection to the animal from the cachectic effects of tumor. Finally, a transgenic tumor that persistently secretes human cachectin was injected into nude mice and, with progressive tumor growth, anorexia, weight loss, and severe cachexia developed that were more severe than in animals bearing a control tumor that did not secrete cachectin.[19] The results demonstrated that long-term, continuous exposure to escalating cachectin levels resulted in severe progressive cachexia and death.[19]

The present study provides additional strong evidence for cachectin as a mediator of cancer cachexia in this rat-tumor experimental model. Cachectin activity was reproducibly detected in the serum of cachectic tumor-bearing rats using the L929 bioassay. Only α-TNF (cachectin) and β-TNF (lymphotoxin) kill these L929 cells. No other cytokine can kill these cells, so the likelihood that cachectin or TNF is present is very high. In addition, cachectin activity was eliminated by high doses of a polyvalent antibody to human cachectin, providing additional evidence that true cachectin activity was measured, and the assay was further verified by measuring appropriate levels in the serum of non–tumor-bearing rats after intravenous administration of recombinant human TNF (Fig 1).

Cachectin activity was not present in the serum of non–tumor-bearing rats, nor in that of tumor-bearing rats, until 28 days after tumor implantation and the growth of the tumor burden to approximately 20% of body weight (Fig 2). Similar cachectic tumor-bearing rats also had inappropriately elevated serum triglyceride levels and cachectin activity levels, suggesting that cachectin was inhibiting the enzyme lipoprotein lipase (Fig 7). In addition, as cachexia progressed (tumor burden increased, food intake decreased, and body weight decreased), cachectin activity in the serum of tumor-bearing rats progressively increased (Figs 3 through 5). Tumor resection that reversed the cachexia (removed tumor and returned food intake and body weight gain to normal levels) also obliterated the elevated cachectin activity levels and triglyceride levels in

Fig 7.—Serum cachectin activity and triglyceride levels of tumor-bearing (closed circles) and pair-fed non–tumor-bearing (open circles) rats before and after tumor resection or sham operation, performed on day 0. Pair-fed non–tumor-bearing rats were given tumor-bearing rats' food intake. Tumor-bearing rats had significantly greater serum triglyceride and cachectin activity levels than pair-fed non–tumor-bearing rats ($P<.005$). Serum triglyceride levels of pair-fed non–tumor-bearing rats were significantly different from those of tumor-bearing rats on postoperative day 7 ($P<.005$).

§$P<.005$ vs control non–tumor-bearing and pair-fed non–tumor-bearing rats.

the serum of the tumor-bearing rat. Pair-fed non–tumor-bearing controls and standard non–tumor-bearing controls indicated that these findings were not due to reduced food intake or operative trauma.

This study demonstrates that experimental cancer cachexia in this rat model is mediated at least partially by a serum factor that has activity like that of recombinant human TNF. The serum factor's activity is blocked by an antibody to human recombinant cachectin and levels increase as cachexia progresses and decrease as cachexia regresses. The idea that an endogenous factor produced in response to an invasive stimulus such as a growing tumor can result in toxic effects on the host provides new insight into the potential pathophysiologic mechanisms of disease and may provide new approaches to disease treatment.

Catherine Gorschboth measured serum triglyceride levels, and Cetus Corp, Emeryville, Calif, provided recombinant human TNF.

Discussion

Q These rats normally have an elevated white blood cell count when their tumors enlarge, and at the same time they become anorexic. Tumor necrosis factor is also associated with an inflammatory response. Is there any way to decide whether this is part of the same inflammatory response or whether this is really something that is produced by tumor?

A These findings may be the result of an inflammatory response. Histopathologic analysis of the tumors showed substantial necrosis and a large number of infiltrating macrophages. This finding is consistent with those of other researchers who have suggested that the in vivo activation of macrophages that respond to tumor with TNF production is due to the tissue necrosis within the tumors.

Q What was body weight change in the non–tumor-bearing animals compared with that in the tumor-bearing animals? In most models, non–tumor-bearing animals that were pair-fed did not lose as much weight.

A We found that non–tumor-bearing pair-fed animals, not only in the present experiment but also in other studies, lost significantly more weight, although the body weight of a tumor-bearing animal includes a large growing tumor in addition to the host weight.

In both non–tumor-bearing rats given exogenous sublethal doses of cachectin/TNF and in anorectic sarcoma-bearing animals, compositional analysis disclosed a loss of total body protein and fat. Yet in the pair-fed control, host protein was saved as a normal physiologic response and only body fat deposits were reduced.

Q Is there any evidence of TNF production by the tumor itself?

A Cell culture of the tumor yielded no detectable cachectin activity, yet Balkwill et al[9] reported finding the message for TNF in two of six colorectal tumors by Northern blot analysis. Currently we have a C-DNA probe for TNF and we are looking for the message within the tumor, its infiltrating macrophages, and its circulating monocytes.

As many as five days after operation these rats still were relatively anorectic, suggesting that the animals still had activated monocytes with continued low levels of cachectin/TNF production. One study reported that only three months after a curative resection did isolated monocytes stop showing increased TNF production in response to a lipopolysaccharide in vitro.

Q What is the clinical importance of the negative TNF trials in patients who are losing weight? There is some evidence to suggest that the interferons may potentiate the effects of TNF.

A Cachectin/TNF is not the only factor responsible for the observed cachexia. We know that TNF induces the production of interleukin 1 and that it, along with other cytokines, can produce the changes we observed. In regard to clinical importance, almost 50% of patients with cancer die of cachexia or have some element of cachexia that plays a role in morbidity. We are studying the value of murine TNF antibodies and have developed a murine TNF antibody to try to reverse the cachexia in tumor-bearing animals. If we can reverse or at least ameliorate the cachexia present in patients with cancer they may have a better response to chemotherapy or operative intervention.

ETHICON* sutures must pass as many as 100 tests before they reach the O.R. to make sure they pass the most important one...YOURS!

ETHICON controls *every* step in the manufacturing process, from raw materials to finished product. And at every step, sutures are rigorously tested: over 100 times in the production of both PROLENE* polypropylene suture and Coated VICRYL* (polyglactin 910) suture. Quality assurance from beginning to end...it's typical of the extra effort we invest in every suture that carries the ETHICON name.

The Flip Side of Tumor Immunity

Richmond T. Prehn, MD, Liisa M. Prehn, MD

• A large amount of data suggest that tumors are, to some degree, dependent for their growth on a positive level of immune reaction, a level that is unique for each tumor. Each tumor gradually adjusts its immunogenicity to the level that will, in the immunologic context of its own particular host, maximize its growth. Thus, it follows that immunosuppression may be as likely as immunoaugmentation to have a therapeutic effect.

(*Arch Surg* 1989;124:102-106)

Some years ago, during the study of the immunogenic properties of hydrocarbon-induced tumors, a puzzling phenomenon was encountered. A number of sarcomas had been produced in mice by the subcutaneous implantation of paraffin pellets containing 3-methylcholanthrene. These tumors were found to vary widely in the strengths of their immunogenicities, some having virtually none while others would refuse to grow in specifically immunized syngeneic hosts.[1] When a variety of similar tumors had reached the size of 1 cm or more, a fragment of tissue was taken from each of two opposite poles of each tumor and transplanted to a different syngeneic recipient.[2] The resulting members of each pair of secondary tumors were compared, either at once or after five to seven transplant generations, for several characteristics, including growth rate, immunizing ability, and susceptibility to an established specific immunity. In a high percentage of cases, the sublines were found to differ, sometimes dramatically, in one or more of these attributes. What had been demonstrated was that each primary tumor, even when shown by antigenic specificity to be of clonal origin, contained within or soon developed, as judged by classic "immunization-challenge" tests, subclones of widely disparate immunogenic characteristics. Despite this heterogeneity, it has been repeatedly observed that tumors can remain highly immunogenic even after extensive in vivo passaging.[3] The change that sometimes does occur is more often a decline of immunizing capacity rather than a change of sensitivity to the immune response.[4] Although immunogenicity (which combines the immunizing ability and the sensitivity to immunity) can be altered by immunoselection,[5] the tumors are usually remarkably stable.[1,2]

Given the heterogeneity in the immunologic properties of the tumor cells, how can one explain, in the face of immune selection, the persistence of immunogenicity through many transplant generations? Why do highly immunogenic tumors tend to remain immunogenic and weakly or nonimmunogenic tumors persist as such? To us, the most satisfactory explanation is that the immunogenicity of a tumor is maintained by immunologic selection at a level close to that which is most conducive to the growth of that particular tumor. The implication is, of course, that the immune reaction is not always inhibitory to the tumor but that, for each tumor, there is a unique level of immune reaction that is optimal for its proliferation; levels of either a greater or a lesser degree would be relatively harmful to the tumor and less conducive to its growth. In other words, immunity has a tumor-facilitating flip side. Please note that what we are discussing is not suppression of tumor immunity, but a positive supportive effect of a certain level of immune reaction on tumor growth.

This theory is supported by the further observation that, among the tumors that had been passaged, there was a significant tendency for a subclone, if its response to a given level of immunity were low relative to that of the other member of the pair, to exhibit a relatively high immunizing capacity.[2] This relationship was not seen when the pairs of sublines obtained directly from the primary tumors were compared. Thus, it appears that the immunizing capacity of a tumor and its sensitivity to the immunity are independent variables; however, presumably because of immunologic selection during passaging, a change in one tends to be compensated by an opposing change in the other, thus tending to stabilize the overall immunogenicity of the tumor.[2]

This idea, that there exists for the growth of each tumor an optimal level of immune reaction peculiar to that tumor, we have called the "immunofacilitation theory"; it has been tested in a wide variety of ways in a large number of different contexts and, in aggregate, these tests have been supportive of the theory.[6] A seeming exception will be discussed after we have outlined the supporting evidence that has accrued, but first we will discuss some general implications of the facilitation theory.

It has been mentioned that, owing to the heterogeneity within each tumor, the immune properties of the tumor will be constantly adjusting to the immunologic environment. Nonetheless, in a vast variety of experimental tumor systems, it has been possible to inhibit tumor growth or to produce cures of established tumors by markedly enhancing antitumor immune reactions. However, these symptoms usually involve a transplanted tumor before it has

been able to undergo much expansion and consequent variation in its new host. In general, because of the problem of heterogeneity, the immunologic approaches to therapy may prove limited; how limited only time and experience will tell. Tumors that have undergone less progression, that are less malignant, and that are treated when small may be more homogeneous and so may offer a better opportunity for immunotherapy. It is also possible that some tumor types may adapt to changes in the immune environment less rapidly than do others.

It follows from the theory that, since each tumor tends to adjust its immunologic variables toward the optimum for that tumor, a therapeutic effect might be produced equally well by either raising or lowering the level of the immune reaction. We have suggested, not entirely facetiously, that chemotherapy may be the best form of immunotherapy[7]! Furthermore, the immunodepression that is often associated with cancer should, perhaps, be considered a host defense-mechanism to which the tumor, unfortunately, soon adapts.

If the tumor tends to be immunologically as well adjusted as we have suggested may be the case, how is it that some tumors will not grow well on transplantation unless the new host is immunosuppressed? The answer probably lies in the fact that the primary host may itself be relatively immunosuppressed by the carcinogen and/or by the tumor. More importantly, because of the manner of antigen presentation in the primary host, the primary autochthonous host is relatively difficult to immunize.[8,9] Consequently, the well-adjusted tumor will usually have a compensatingly higher immunogenicity than will be optimal for it in a new secondary host.

There is ample evidence that changes in the immune capacities of the animals can profoundly influence oncogenesis in many experimental systems[10,11]; how is this to be explained if tumors are immunologically so adaptable? In the instructive example of two-stage skin tumorigenesis, it has been shown that many initiated cells lie dormant for long periods and may never give rise to a tumor.[12] It has also been shown that the immunogenicity of tumors tends to be directly related to the concentration of carcinogen even in the absence of immunologic selection.[13] Therefore, whether an initiated cell progresses to overt tumor will depend, at least in part, on the antigenicity of the clone in relation to the immunologic characteristics of the host. Adaptation, via selection, cannot occur until after cellular proliferation has produced heterogeneity among the tumor cells.

The incidence of some tumors in the human may also be markedly altered by altering the immunocompetences of the hosts. Thus, when humans are immunosuppressed for kidney grafting, the incidence of skin tumors is increased.[14] Presumably, this is a different spectrum of tumors, with a compensatingly different sensitivity to immune reactions, than that which occurs in the skins of immunologically normal people. The fact that the tumor incidence is increased suggests, however, that the skin of a normal person is overly reactive for optimal growth of the average clone of potential skin tumor cells; the tumors that are actually realized in normal skin are probably derived from an immunologically selected minor subpopulation of less immunogenic clones. The remainder remain dormant, presumably because of the lack, for them, of a sufficiently propitious immune environment.

In the human, the observation of an increased cancer incidence among patients with immunodeficiency has been confined to a relatively few tumor types, most notably ultraviolet-induced skin tumors, among patients immunosuppressed for allografting, and Kaposi's sarcoma among patients with acquired immunodeficiency syndrome.[14,15] (The increased incidence of tumors of the immune system per se, ie, lymphoid tumors, may have little to do with a changed immune reaction against the tumors and thus should probably not be considered in the present context.) Why is it that the incidences of a greater variety of human tumors are not overtly influenced by an immunodepressed state? A likely explanation is that those few tumor types whose incidences are increased by immunodepression are, indeed, the only human tumors of which most of the originally transformed precursors were so immunogenic that they were not immunologically stimulated to grow in the absence of immunodepression (classic immunosurveillance?). The remaining less immunogenic types would actually, according to the facilitation hypothesis, tend to appear less often in immunodepressed patients or more often if immunity were augmented rather than reduced. According to the theory, both the more and the less immunogenic types are dependent on the immune reaction, but the optimal level of the immunity differs. For example, although Kaposi's sarcoma is a common feature of the acquired immunodeficiency syndrome, it is apparently associated with the less severe cases.[16,17] This probably means that the tumor, although it grows best in the immunologically compromised patient, is, nonetheless, dependent on the presence of an immune reaction, albeit a level of reaction less than that which can be mounted by a normal person.

It has been observed in some human tumor systems that the degree of local immunologic reactivity at the tumor site is directly correlated with a good prognosis. This has been especially noted in breast cancer.[18] How is this to be explained in terms of the immunofacilitation hypothesis? Perhaps in some cases the immune reaction does become greater than is optimal for tumor growth. In others, however, we suggest that the tumor, which is actually dependent on the immune reaction, loses its dependency during its biologic progression, much as a hormonally dependent tumor tends with time to lose its dependence on the relevant hormone.[19] The lack of leukocytic reactions around melanoma metastases, for example, is in striking contrast to the usually heavy infiltrations around early lesions. The good prognosis that is associated with an immunologic reaction may, therefore, be an association and nothing more; the reaction may be merely a marker of a tumor that is still early in its biologic progression and still in its dependent phase. A tumor that is early in its progression would have a relatively good prognosis because of this fact, not because of the immune reaction that is also associated with the early stages of progression.

Recently a seemingly paradoxical set of observations was published concerning the biology of human malignant melanomas. It was found that the prognosis of superficial cutaneous lesions was relatively poor if these lesions underwent substantial spontaneous regression. Similar lesions, if they did not show regression, seldom metastasized and were not dangerous.[20] Apparently, the stronger the host's reaction to the primary lesion in the skin, the more likely the growth of metastases. While a number of hypotheses could probably be advanced to explain the paradox, we are intrigued by how well it may be explained by the immunofacilitation theory.

Recent work from other laboratories with different tumor systems suggest that the cells that metastasize may not always differ in any significant way from the cells that remain in the primary lesion.[21,22] Therefore, different behaviors, such as simultaneous growth of a metastasis and

regression at the primary site in the skin, may be due to differences in the anatomic sites rather than to differences in the tumor cells. To explain the paradox of the behavior of cutaneous melanomas, one has simply to add the fact, which few immunologists would dispute, that the skin probably has a much more potent intrinsic immunologic mechanism than do most other organs. Therefore, the melanoma, which evolved to grow within the strong immunologic environment of the skin, would grow poorly, if at all, in the relatively deficient immunologic environment of one of the internal organs. However, if, by chance or immune manipulation,[23] the host became more reactive than was optimal for the melanoma's in situ growth, the host might be so reactive that the melanoma could grow in a more immunologically deficient site.

A second and not mutally exclusive explanation of the paradoxical growth of melanomas is that the vigorous immune response in the skin causes, either by selection and/or actual mutation,[24] the development of variant clones that are less dependent on the immune response and can, therefore, grow in more immunologically deficient internal organs.

In our laboratory, we have made four distinctly different types of experimental challenges to the immunofacilitation theory.[6] The first was to attempt titrations of the immune reaction, both in vivo and in vitro, and then to determine the effect on tumor growth and/or on oncogenesis. For example, it was found that mice that had undergone thymectomy as adults, exposed to 450 rad of whole-body radiation, and then immunologically restored to varying extents by giving various dosages of normal syngeneic spleen cells were most susceptible to sarcogenesis with 3-methylcholanthrene when the spleen-cell dosage was at an intermediate level.[25] In other words, the mice that had been restored to a modest extent were more susceptible than were those that had been restored either minimally or maximally. Numerous other experiments along similar lines were done with similar results, both in our own laboratory and by others.[19,26-33] Perhaps the nicest work was done by Shearer and Parker,[30] who showed that a similar result could be found by titrating specific antibody against the growth of tumor cells both in vivo and in vitro. The conclusion from these studies was that a modest, rather than a minimal, immune reaction was usually most conducive to tumor growth; a larger reaction could, of course, be inhibitory.

The second and quite different method of challenging the hypothesis was based on the observation, in the mouse, that there exists a relationship between the original latency of a chemically induced tumor in the primary autochthonous host and its immunogenicity as shown by subsequent transplantation tests in syngeneic animals. A detailed reexamination of this relationship showed that the tumors of shortest latencies had intermediate levels of immunogenicity.[34] Tumors that had had longer latencies in the original hosts tended to have either higher or lower immunogenicities. Ancillary work suggested that the differing latencies among the tumors were a direct consequence of the differing levels of immune reactivity.[34] Thus, it again could be concluded that the optimal level of immune reaction for rapid oncogenesis was not minimal but intermediate.

The third method was based on the previously established fact that, even among mice genetically able to metabolize the carcinogen to its active form, there exist, among different strains, large differences in susceptibilities to tumor induction. Most remarkably, it was found that the mouse strain most susceptible to tumor formation by a large concentration of 3-methylcholanthrene, in subcutaneously placed paraffin wafers, was the strain least susceptible to a low concentration, and vice versa.[35] The rank order of susceptibilities, across as many as ten different genotypes, was found to reverse when the concentration of carcinogen was changed from high to low. Subsequent work suggested that the rank-order–reversal phenomenon was dependent on an intact immune system,[36] and it was already known that, when the chemical was administered in paraffin wafers, the immunogenicities of the tumors tended to be directly related to the concentration of carcinogen.[37] The most reasonable interpretion of these findings seems to be that optimal oncogenesis was produced by combining high tumor immunogenicities, as produced by high concentrations of carcinogen, with a strain of mouse with relatively low immune capacity, and vice versa. Thus, oncogenesis was favored by an intermediate level of antitumor immune reaction.

The fourth and last method of challenging the hypothesis that a modest immune reaction is a positive aid to tumor formation is the observation that thymectomy of the 3-day old mouse, which, in contrast to thymectomy at birth or at 7 days of age, causes hyperplastic autoimmune lesions,[38] increases susceptibility to subsequent chemical carcinogenesis.[39] It was observed that this increase in susceptibility occurred only with low concentrations of chemical; with higher concentrations, thymectomy at 3 days of age inhibited tumor formation.[39] Once again it seems that an elevated immune capacity, as evidenced by the tendency to the development of autoimmune lesions, aided oncogenesis only when the tumors were of the relatively low immunogenicity type that are characteristic of low concentrations of carcinogen. The parallels with the "reversal phenomenon" are striking.

The apparent correlation between experimental autoimmunity and susceptibility to low-dose oncogenesis[39] and the association of many autoimmune diseases in the human with an increased risk of cancer[6] suggest the hypothesis that increased autoimmune reactivity may often be a causative factor in oncogenesis. It appears that partial immunologic crippling, whether produced by aging,[40] radiation,[41,42] or a variety of other factors,[43,44] may sometimes result in a decline of the suppressor cells that is greater than the decline of the effectors; this differential decline may be especially true of the suppressors of various antiself reactions. The resulting autoimmunity is apparently conducive to oncogenesis with low dosages of carcinogen.[39] In other words, cancer may be, at least in part, an autoimmune disease.[6]

The hypothesis that immunity can be a positive aid to tumor growth is not new, but it is only within the last decade that the evidence supporting it has become persuasive. The consistency of the results obtained with such disparate approaches as we have described seems, to us, to make a virtually conclusive case in favor of the hypothesis, but the mechanisms are not clear. Recent evidence has implicated the macrophage, which is now known to be capable of secreting growth-promoting factors.[45-47] Recently, work by Tsuda et al[48] has shown that the slower growth of tumors in aged mice is caused, at least in part, by a deficiency of certain tumor-facilitating lymphocytes. However, the work of Shearer and Parker[30] with antibody suggests to us that perhaps any immune effector can facilitate tumor growth if the quantitative relationships are correct.

Although the evidence for the immunofacilitation theory seems, for the most part, strong and consistent, there is one set of observations that was at first troubling. It has

been observed repeatedly, and in a number of different tumor systems, that many transplanted tumors do not grow well in nude mice.[49] This is not because of a lack of an immune system, as the facilitation theory would, at first consideration, probably suggest; immunogenic, and only immunogenic, tumors grow better if the nude mice are first irradiated or otherwise presumptively further immunodepressed.[50] This is so despite the fact that nude mice are, without irradiation, already incapable of rejecting a nonmalignant allograft or zenograft.[49] Tumors that exhibit this behavior include methylcholanthrene-induced sarcomas of the type that were used to demonstrate that there is, for each tumor, some positive level of immune reaction that is conducive to tumor growth.

One possible explanation for the behavior of transplanted tumors in nude mice, which is consistent with the immunofacilitation theory, assumes that immunity to normal-tissue xenografts and allografts is, per se, qualitatively different from some facet of antitumor immunity and that the nude mouse has an excess of the latter.[49] Although the antitumor facet of the immune reaction in nude mice is excessive for many transplanted tumors, it is suboptimal for skin carcinogenesis with 3-methylcholanthrene,[51] a fact that again probably illustrates the profound importance of the manner of antigen presentation. The antitumor reaction of the nude mice could be dependent in part on natural killer cells, which nude mice have been shown to possess,[52] but since the radiosensitive resistance in the nude mice correlates with the presence in the tumors of specific immunogenicity (in normal mice), a role for tumor-specific antigens is implied.[50] This explanation suggests that irradiation of the nude mouse reduces a putative antitumor immunity nearer to an optimum, but possibly still positive, level for tumor growth. Even were the antitumor immunity completely abolished by irradiation, the transplanted tumor might still be expected to grow better than it would in the face of the excessive amount of antitumor activity that is postulated to exist in the unirradiated adult nude mouse.

The apparent fact that immunity can be either stimulatory or inhibitory to tumor growth, depending on quantitative factors—that immunity has a flip side—is, in our minds, a serious complication to immunologic approaches to therapy and may help to explain why immunologic approaches have not as yet lived up to their seeming potential. Hopefully, the knowledge of the existence of this complication will make the creation of more successful immunologic strategies feasible. Progress would seem to depend on developing a way of assessing the individual tumor's sensitivity to immunity and whether the host's response is higher or lower, in vivo, than is optimal for the growth of that tumor. We think it encouraging that tumors of little immunogenicity that are induced by very low dosages of carcinogen, and therefore perhaps most human tumors, can be influenced, albeit not as yet to the host's advantage, by immunomodulation[39]; we are encouraged to believe that when tumor immunity can be abrogated specifically, a therapeutic effect may be achieved with many tumors, especially early in their progression. Until that time, cautious trials of less ideal immunosuppressants, such as cyclosporine, might be useful. Presently available data suggest that cyclosporine may not be more harmful to the cancer patient than to the transplant patient[53]; it has been shown, under some conditions, to be a successful adjunct to chemotherapy[54] and to interfere with experimental metastases, perhaps by a direct cytotoxic effect on tumor cells.[55,56] The fact that cyclosporine increases the incidence of some types of tumor[14] and can, under some conditions, produce autoimmunity[43] does not necessarily mean that it cannot be used for therapy. In its favor is the fact that it can be of benefit in the hyperplasia of psoriasis, although its efficacy in that disease may be attributable to a direct cytotoxic effect on keratinocytes rather than to immunologic effects.[57] In any case, immunosuppressive therapy seems fully as rational as immunoaugmentive; we would anticipate some striking successes, but many tumors will probably adapt and thus escape from either immunosuppression or immunoaugmentation.

Tetracycline for Sclerosis of Thyroid Cysts: A Randomized Study

Laszlo Hegedüs, MD; Jens Mølhom Hansen, MD; Steen Karstrup, MD; Søren Torp-Pedersen, MD; Niels Juul, MD

In a prospective study, 53 consecutive patients with solitary thyroid cysts were randomized to ultrasonically guided cyst aspiration and subsequent flushing with isotonic saline (n = 30) or tetracycline hydrochloride (n = 23). The patients were followed up clinically and ultrasonically 1, 3, 6, and 12 months after treatment. If the cyst recurred, a repeated treatment was offered. Cure was defined as the absence of any residual nodule and an ultrasonic cyst volume of less than 1 mL 12 months after the last treatment. During follow-up, two patients without recurrence after saline treatment and six patients without recurrence after tetracycline treatment developed solid cold nodules. Fourteen (47%) of 30 patients in the saline group and ten (43%) of 23 patients in the tetracycline group were cured (not statistically significant). Tetracycline does not seem to offer any advantage over isotonic saline in the treatment of thyroid cysts, and some of these patients still need thyroid surgery (*Arch Intern Med* 1988;148:1116-1118).

Recombinant Human Tumor Necrosis Factor Alone and With Chemotherapeutic Agents

Effect on Nude Mouse–Supported Human Bladder Cancer Heterografts

Anurag K. Das, MD; Philip J. Walther, MD, PhD; Niall J. Buckley, MD; Susan H. M. Poulton

• Although studies done in tissue culture (in vitro) have shown synergism between recombinant human tumor necrosis factor (rhTNF) and chemotherapeutic agents, whether such synergism exists in a complex in vivo environment with acceptable toxic side effects has not been determined, to our knowledge. The effect of rhTNF alone and in combination with cisplatin, etoposide, doxorubicin, or dactinomycin on the growth of heterotransplants of human bladder transitional cell carcinoma was studied using a modified subrenal capsule assay in athymic nude mice. Only etoposide potentiated rhTNF cytotoxicity; no increase in host toxicity was noted. Variably enhanced toxic side effects were seen with other combinations. It is concluded that rhTNF combined with etoposide may have potential clinically exploitable therapeutic "synergism" in the treatment of advanced bladder cancer.

(*Arch Surg* 1989;124:107-110)

Tumor necrosis factor (TNF) is a polypeptide found in the serum of animals sensitized to an immunopotentiator such as BCG and then challenged with endotoxin.[1] Tumor necrosis factor is produced by macrophages both in vivo and in vitro and has been shown to cause hemorrhagic necrosis of some tumors when passively transferred to tumor-bearing animals.[1,2] With the availability of relatively pure recombinant human TNF (rhTNF), in vivo and in vitro chemosensitivity studies have been carried out testing the effectiveness of rhTNF alone and in combination with chemotherapeutic and immunotherapeutic agents.[3-6] While in vivo assays against some syngeneic mouse tumors have resulted in complete tumor regression after TNF therapy, treatment of animals with human tumor xenografts has not been as effective. Although intralesional injections of TNF directly into the tumor have provided significant tumor regression and an occasional complete cure,[7] this is not a particularly valuable method for measuring antineoplastic agent effectiveness. Intravenous or intraperitoneal TNF alone has some cytotoxic effect on human tumor xenografts but seldom results in significant tumor regression.[3,5,7,8] Since rhTNF alone is believed to have few toxic side effects,[3,9] it would seem to be an ideal agent to use in combination with chemotherapeutic agents if it enhanced the tumor cytotoxicity–host toxicity ratio.

In vitro studies have shown TNF effectiveness against a variety of human transformed and nontransformed cell lines.[4,9,10] Dactinomycin has long been known to modify the cytotoxicity of TNF and this combination has become the standard to define TNF activity. Why dactinomycin significantly enhances TNF cytotoxicity is not known, although inhibition of RNA synthesis is postulated to be the major mechanism.[11] Recently, synergistic enhancement by TNF of the in vitro cytotoxicity of chemotherapeutic agents targeted at DNA topoisomerase II has been reported[6]; the most commonly used agents targeted at DNA topoisomerase II include dactinomycin, doxorubicin, and etoposide (VP-16). To our knowledge, the mechanism of this enhanced cytotoxicity remains unknown. However, whether any potentiation of either tumoricidal efficacy or host toxicity (two components of the "therapeutic index") occurs when these drugs are combined with TNF in the complex in vivo pharmacologic milieu is not known; such issues require the use of an animal model.

We studied the effects of purified rhTNF alone and in combination with three drugs targeted at DNA topoisomerase II—dactinomycin, doxorubicin, and etoposide—and one drug that is not—cisplatin, but that has known efficacy in the therapy of bladder carcinoma. Both the cytotoxicity and the toxicity of each agent alone and in combination were examined using tumor xenografts of human bladder transitional cell carcinoma—a tumor believed to be biologic response modifier sensitive. To perform the testing we used our modified nude mouse subrenal capsule assay (MSRCA)—a precise, rapid, in vivo chemosensitivity assay.

MATERIALS AND METHODS

Cytotoxic Agents

Patient grade sterile preparations of cisplatin (Platinol), doxorubicin hydrochloride (Adriamycin), etoposide (VePesid), and dactinomycin D (Cosmegen) were utilized for this study and prepared fresh using the manufacturer's recommendations. The rhTNF used had a purity of 95% by sodium dodecyl sulfate/polyacrylamide gel electrophoresis. Endotoxin contamination was minimal, 0.058 ng/0.29 mg of protein by *Limulus* amebocyte lysate assay, and the bioactivity was 22 413 U/μg of protein. It was prepared using bovine serum albumin (BSA) as a carrier protein according to the manufacturer's recommendation and stored at −20°C before reconstitution and −70°C after reconstitution.

Human Tumor Xenografts

Human tumor heterotransplants of a bladder transitional cell carcinoma tumor line (DU-4284) have been maintained by serial subcutaneous passages in nu/nu athymic nude mice. Nude mice were all from our inbred breeding colony designated BALB/c AnBom Urd and were maintained in the Animal and Laboratory Isolation Facility (a true barrier facility) of Duke University Medical Center, Durham, NC. The tumor line was established from a lymph node metastasis in a patient with high-grade transitional cell carcinoma and was used in its 18th passage. It has a subcutaneous doubling time of four days. Tumor was removed from mice and kept bathed in RPMI-1640 until it was implanted in mice, usually within two to three hours.

MSRCA

Eight-week-old nude mice from our breeding colony were used for all experiments. Since the subrenal capsule in mice is transparent, implanted tumors can be measured in situ. The implantation technique has been previously described.[12] A system that employs a stereoscopic zoom microscope (Olympus model SZH, Olympus Corporation, Lake Success, NY) with an ocular micrometer was used at ×11.4 magnification such that 1 mm was equivalent to 11.4 ocular units. The length and width of each implant were recorded in ocular units. Briefly, the following protocol was observed.

Day 1.—Initial body weight was taken after mice were anesthetized with pentobarbital sodium. Using sterile technique, a 1.5-cm incision was made over the left flank and the kidney was exteriorized. A small incision was then made in the transparent

capsule; fine forceps were used to place a 0.75-mm³ piece of tumor, and exact measurements were determined using the ocular micrometer. The kidney was then replaced and the incision closed with clips.

Day 6.—Mice were anesthetized, clips were removed, kidneys were exteriorized, and, using the ocular micrometer, precise measurements of tumor length and width were noted before reclosure. Volume determinations of the tumor at day 1 and day 6 were made using the formula for a spheroid. Any mice whose tumors had regressed from day 1 to day 6 were rejected at this point. The remaining mice were then randomized into groups of eight.

Days 7 Through 9.—Therapy was administered according to the doses shown in Table 1. Controls received 0.1 mL of intravenous 2% BSA. When a combination of TNF and chemotherapeutic agents was used, the chemotherapeutic agent was always given approximately one hour before the TNF. The TNF was always given intravenously (volume, 0.1 mL), while chemotherapeutic agents were always given intraperitoneally in a volume of 0.2 to 0.3 mL.

Day 11.—Mice were killed, weighed, and tumor-bearing kidneys were excised. Final length and width measurements were determined before samples of tumor-bearing kidneys were sectioned and stained for microscopic examination.

Analysis of Data

Analysis of Tumor/Cohort Consistency.—After tumor volume determinations at days 1, 6, and 11 had been made, day 6/day 1 and day 11/day 6 growth ratios were calculated. These were analyzed using the nonparametric Kruskall-Wallis one-way analysis of variance.[13] This analysis confirmed that all cohorts were not statistically significantly different (text statistic [T] = 10.40, $P = .49$) prior to therapy (day 6/day 1), while after therapy (day 11/day 6), there were statistically significant differences among the cohorts (T = 23.51, $P = .01$).

Relative Tumor Survival (RTS).—This was calculated using the formula $(R_T/R_C) \times 100$ where R_T is the day 11/day 6 ratio of a treated cohort and R_C is the day 11/day 6 ratio of the control (BSA) cohort. By definition, then, the controls (BSA) have 100% tumor survival. To determine if there were any statistically significant differences between certain cohorts, the nonparametric Mann-Whitney U test[13] was used since the data include percentages and are not normally distributed.

Analysis of Potential Synergism.—To determine possible synergism, the actual RTS values for chemotherapeutic drug plus rhTNF were compared with predicted relative survival values. Predicted relative survival values were determined by multiplying the RTS values of rhTNF alone and the chemotherapeutic drug alone. For example, the RTS for etoposide alone is 59%, for rhTNF alone is also 59%, and the predicted RTS for etoposide plus rhTNF is then 34%.

All data were analyzed using a statistical graphics system (STATGRAPHICS, Statistical Graphics Corporation, Rockville, Md).

RESULTS

Host Toxic Side Effects

Table 1 shows the mortality and weight loss for mice treated with combinations of chemotherapeutic agents and rhTNF. There was no significant mortality or weight loss from rhTNF therapy alone. There was also no significant change in mortality of cohorts treated with etoposide alone and etoposide plus rhTNF and cisplatin alone and cisplatin plus rhTNF. However, the weight loss in doxorubicin alone cohorts was only 1.9% compared with 15% in doxorubicin plus rhTNF cohorts, signifying increased morbidity. While dactinomycin *alone* had a mortality of 0% and a weight loss of 7.6%, dactinomycin plus rhTNF had 100% mortality. This suggests that the lethal toxicity is by a mechanism not related to cachexia.

Dose/Schedule Analysis of rhTNF Cytotoxicity

Figure 1 shows the actual growth curves of different rhTNF treatment regimens assessed using the MSRCA. Relative tumor survival defined above is tabulated in Table

Fig 2.—Effect of etoposide and recombinant human tumor necrosis factor (rhTNF) alone and in combination with DU-4284 in nu/nu athymic nude mice. Solid circles indicate control (2% bovine serum albumin); open triangles, etoposide 45 mg/kg intraperitoneally (IP) on days 7 and 8; open squares, rhTNF 50 μg/kg on days 7 and 8; and solid triangles, etoposide 45 mg/kg IP on days 7 and 8 and rhTNF 50 μg/kg intravenously on days 7 and 8.

Fig 3.—Effect of doxorubicin and recombinant human tumor necrosis factor (rhTNF) alone and in combination on DU-4284 in nu/nu athymic nude mice. Solid circles indicate control (2% bovine serum albumin); open triangles, doxorubicin 12 mg/kg intraperitoneally (IP) on day 7; open squares, rhTNF 50 μg/kg intravenously (IV) on days 7 and 8; and solid triangles, doxorubicin 12 mg/kg IP on day 7 and rhTNF 50 μg/kg IV on days 7 and 8.

2. Multiple-dose rhTNF was moderately effective alone in doses that caused no significant toxic side effects.

Analysis of Single Antineoplastic Agent Cytotoxicity Alone and in Combination With rhTNF

Figures 1 through 4 depict the actual growth curves for etoposide, cisplatin, and doxorubicin alone and in combination with rhTNF. The RTS values are shown in Table 2. Cisplatin was the most effective drug (RTS, 41%), while dactinomycin was the least effective (RTS, 73%). The Mann-Whitney U test revealed a statistically significant difference between the etoposide only and etoposide plus rhTNF cohorts ($P=.0019$). No statistically significant differences were noted in the cisplatin alone and cisplatin plus rhTNF cohorts ($P=.52$) or in the doxorubicin alone and doxorubicin plus rhTNF cohorts ($P=.12$).

Analysis of Synergism

To determine possible synergism, the predicted RTS of rhTNF in combination with a particular chemotherapeutic agent was compared with the actual RTS. The actual and

Fig 4.—Effect of cisplatin and recombinant human tumor necrosis factor (rhTNF) alone and in combination on DU-4284 in nu/nu athymic nude mice. Solid circles indicate control (2% bovine serum albumin); open triangles, cisplatin 6 mg/kg intraperitoneally (IP) on days 7 and 8; open squares, rhTNF 50 μg/kg intravenously (IV) on days 7 and 8; and solid triangles, cisplatin 6 mg/kg IP on days 7 and 8 and rhTNF 50 μg/kg IV on days 7 and 8.

Table 3.—Predicted and Actual Relative Tumor Survivals

	Relative Tumor Survival, %	
	Predicted	Actual
Etoposide + rhTNF*	34	28
Cisplatin + rhTNF	27	41
Doxorubicin + rhTNF	34	49

*rhTNF indicates recombinant human tumor necrosis factor.

predicted RTS values for the three agents are shown in Table 3. Only etoposide demonstrated an actual RTS (28%) that was less than the predicted RTS (34%), thus fulfilling the definition of therapeutic "synergism."

COMMENT

While chemotherapeutic agents exert direct cytotoxic metabolic effects on dividing cells, biologic response modifiers as a class usually exert a tumor cytotoxic effect via a receptor either directly and/or by activation of host cells.[4] While normal cells seem to be immune to the cytotoxic effects of rhTNF, the exact mechanism of tumor cytotoxicity remains unclear.

Although potentiation of rhTNF tumor cytotoxicity has been reported in in vitro experiments, particularly when used in conjunction with chemotherapeutic agents targeted at DNA topoisomerase II, in vitro assays do not provide any measure of the possible increased toxic side effects when combinations of agents are used ("therapeutic index"). Alexander et al[6] demonstrated enhanced cytotoxic activity of rhTNF in combination with dactinomycin over a wide variety of concentrations. However, doxorubin enhanced rhTNF cytotoxicity only at concentrations above 10 mg/L. The peak achievable plasma concentration of doxorubicin is believed to be 0.6 to 1 mg/L,[14] suggesting that doxorubicin potentiation of rhTNF may not be clinically applicable; our results would confirm this.

Our nude mouse in vivo assay demonstrated a statistically significant difference between the etoposide plus rhTNF and the etoposide alone cohorts. The extent of this difference would suggest potentiation, ie, synergism of tumor cell kill. While the definition of drug synergism in an in vivo system is a difficult question,[15-17] our actual RTS for the etoposide plus rhTNF cohort was, using the

Drewinko et al[18] approach adapted to an in vivo situation, less than the predicted RTS, thereby fulfilling such criteria for synergism. No such difference was noted with either cisplatin or doxorubicin, since the actual RTS for both these drugs was greater than the predicted tumor survival. Thus, of three drugs tested that are targeted at DNA topoisomerase II, one (etoposide) potentiates rhTNF cytotoxicity without increased host toxicity, one (doxorubicin) has little or no effect on potentiating rhTNF cytotoxicity while slightly increasing host toxicity, and one (dactinomycin) greatly increases host toxicity. Cisplatin, which is not targeted at DNA topoisomerase II, had little effect at the doses used either in potentiating TNF cytotoxicity or in increasing host toxicity.

The marked toxicity of dactinomycin in combination with rhTNF was surprising since the toxicity of dactinomycin alone was minimal. Although dactinomycin is believed to inhibit RNA synthesis as well as act on DNA topoisomerase II,[11,19] its primary mechanism of increased toxicity in combination with rhTNF remains poorly understood. This suggests the possibility that "toxic synergism" may also exist where the therapeutic index could conceivably be worsened. Thus, whether dactinomycin is of any value in combination with TNF (as assessed in this assay system) is still unknown to our knowledge, although further efforts in addressing the toxicity of dactinomycin plus rhTNF are presently ongoing.

Doxorubicin did not potentiate rhTNF activity at the dose used while it did cause some increase in host toxicity. However, we had carefully chosen our clinically relevant doses based on previous toxicity studies such that drug-alone doses would have minimal toxic side effects while achieving some tumor kill, and thus either increased toxic side effects or increased tumor kill would be easily identifiable when drugs were used in combination with rhTNF. Therefore, although doxorubicin may enhance the effectiveness of rhTNF at higher doses, it will probably do so only at unacceptable toxicity levels.

Of the four, etoposide, a nonintercalating epipodophyllotoxin, shows promise as an agent to be used in combination with rhTNF, since its increased tumor cell kill without any increase in host toxicity in the doses studied. Since in vitro studies had shown that the drug must precede treatment with rhTNF,[6] the drugs were always administered one hour prior to therapy with rhTNF. Further dose- and time-related studies with the etoposide and rhTNF combination seeking to arrive at optimal dose and time schedules will be necessary and are ongoing.

In conclusion, we have developed an in vivo animal system that would appear to be an excellent model for the study of potential synergism of cytotoxic agents with rhTNF for the treatment of human bladder carcinoma. It also may be applicable for the study of other human malignant neoplasms that have been adapted into an athymic nude mouse host. Using this approach, the combination of etoposide and rhTNF appears promising for potential clinical utilization. In vivo studies to determine ideal time and dose schedules in this animal model may assist in the design of clinical trials.

This investigation was supported in part by a grant from Merit Review, Veterans Administration Research Service, Durham, NC, and the CURED Foundation, Duke University, Durham.

Human RhTNF was provided by Cetus Corp, Emeryville, Calif.

Discussion

Q Your data show that etoposide was the only agent that seemed to be effective and the others were not. How might you explain your observation?

A Well, the initial in vitro data published by Alexander et al[6] showed that dactinomycin, doxorubicin (Adriamycin), and etoposide (VP = 16) were all effective. However, if you look at their data closely they show that only dactinomycin is really effective at low doses and doxorubicin is effective at doses that are not clinically achievable. It may well be that doxorubicin is effective at higher doses, but these doses would probably cause so many toxic side effects that one would not see the effectiveness.

Q I was interested in your very distinct toxic reactions with dactinomycin. In the older literature, in some of the in vitro assays dactinomycin was used to supplement the TNF effect. These studies would try to set the stage by sensitizing cells with dactinomycin and then check for TNF activity. It is very intriguing that you are showing such a dramatic synergism between the two, even though it is a lethal synergism, and one would wonder if whether it's just the dosage that you use. Maybe with a lesser dose you might get antitumor activity.

A Dr Buckley, one of our coauthors, is going to be presenting a paper at the American Association for Cancer Research that looks at full-dose response curves of dactinomycin and TNF, starting at much lower dose levels and progressing upward. His data essentially show that there is a dose-response curve and if you drop the dactinomycin dose down to levels of 0.1 and 0.25 mg/kg, there is much less toxic reaction, but the toxic side effects are more dependent on the dactinomycin than the TNF. With this particular dose of dactinomycin, even with much lower doses of TNF, you still get significant toxic reactions. Since we did not see much response to dactinomycin at this dose alone, we doubt that with much lower doses of dactinomycin plus TNF one would see any kind of a tumor response.

Announcing The Tenth Annual American Medical Association

Morris Fishbein Fellowship

July 1, 1989 through June 30, 1990

Applications are now being taken for the Tenth Annual Morris Fishbein Fellowship in Medical Journalism sponsored by the American Medical Association. Physicians interested in making a substantial commitment to medical journalism are invited to apply for this full-time one-year fellowship program.

Work With JAMA The successful candidate will work with the editorial and production staff of The Journal of the American Medical Association in all facets of editing and publishing a major weekly medical journal. At the completion of the program, it is expected that the candidate will be proficient in all aspects of manuscript selection, issue makeup, copy editing and styling, art and layout of articles, issue planning and managing, in addition to the many other elements of journal publication. He/she will also be conversant with marketing and advertising procedures.

Publishing The candidate must have proved writing ability at the time of application, for he/she will be required during the course of the year to prepare such articles for publication as may be assigned. Although the fellow will work under the supervision of a physician-editor, ability to work independently is a must. Ability to use a resource library is a strong plus.

Specialty Journal Opportunity In addition to The Journal of the American Medical Association, the Fishbein Fellow will receive special insight into the different aspects of publishing a major specialty journal on a monthly timetable.

Stipend A stipend of $30,000 will be provided to the successful candidate to cover the 1-year period.

Application Forms For an application blank, please write to: Helene M. Cole, MD, Senior Editor, Director, Department of Editorial Affairs, Journal of the American Medical Association, 535 N. Dearborn St., Chicago, IL 60610.

Deadline For Applying Completed applications should be forwarded as soon as possible and must be received no later than January 15, 1989. The successful candidate will be notified by March 31, 1989.

She's outbattled the Great Depression, her husband's death, and a myocardial infarction.
Now she's won a fight against cholecystitis.

SQUIBB

At risk for aminoglycoside toxicity:

The elderly.

*AZACTAM — safer than aminoglycosides for elderly patients**

For a variety of reasons, including their often debilitated condition and serious underlying diseases, elderly patients have been reported to be at increased risk for aminoglycoside-associated toxicities.[1] AZACTAM represents a safer alternative for the treatment of gram-negative infections in these patients, an alternative that is free from the risks of nephrotoxicity† and ototoxicity.[2-5]

AZACTAM — the first monobactam — as effective as the aminoglycosides

In addition to its increased margin of safety, AZACTAM offers clinical and microbiological effectiveness equal to aminoglycosides in the treatment of gram-negative infections, such as peritonitis, intraabdominal abscess, and gangrenous appendicitis.[6-8] Its bactericidal activity is well suited for monotherapy when a susceptible gram-negative pathogen has been identified and is an ideal complement to gram-positive or anaerobic agents when empirical therapy is indicated.

**Dosage adjustment, based on estimated creatinine clearance, may be necessary in elderly patients.*
†Demonstrated in animal studies and in human volunteer studies. In clinical trials involving 4,570 subjects, transient elevations in serum creatinine were rarely observed.

For a discussion of INDICATIONS AND USAGE (including susceptible organisms), CONTRAINDICATIONS, WARNINGS, PRECAUTIONS, and ADVERSE REACTIONS, please consult brief summary on the following page.

The logical alternative to aminoglycosides

Azactam® instead.

aztreonam

The logical alternative to aminoglycosides

Azactam® instead.

aztreonam

AZACTAM® FOR INJECTION
Aztreonam For Injection

DESCRIPTION—AZACTAM (aztreonam, Squibb) is the first member of a new class of antibiotics classified as monobactams. AZACTAM is a totally synthetic bactericidal antibiotic with activity against a wide spectrum of gram-negative aerobic pathogens. The monobactams, having a unique monocyclic beta-lactam nucleus, are structurally different from other beta-lactam antibiotics.

AZACTAM For Injection is a sterile, nonpyrogenic, sodium-free, white to yellowish-white lyophilized cake, containing approximately 780 mg arginine per gram of aztreonam for intramuscular or intravenous use following constitution. Aqueous solutions of the product have a pH in the range of 4.5-7.5.

INDICATIONS AND USAGE—Before initiating treatment with AZACTAM, appropriate specimens should be obtained for isolation of the causative organism(s) and for determination of susceptibility to aztreonam. Treatment with AZACTAM may be started empirically before results of the susceptibility testing are available; subsequently, appropriate antibiotic therapy should be continued.

AZACTAM For Injection is indicated for the treatment of the following infections caused by susceptible gram-negative microorganisms: **Urinary Tract Infections** (complicated and uncomplicated), including pyelonephritis and cystitis (initial and recurrent) caused by *Escherichia coli, Klebsiella pneumoniae, Proteus mirabilis, Pseudomonas aeruginosa, Enterobacter cloacae, Klebsiella oxytoca**, *Citrobacter* species* and *Serratia marcescens**. **Lower Respiratory Tract Infections,** including pneumonia and bronchitis caused by *Escherichia coli, Klebsiella pneumoniae, Pseudomonas aeruginosa, Haemophilus influenzae, Proteus mirabilis, Enterobacter* species and *Serratia marcescens**. **Septicemia** caused by *Escherichia coli, Klebsiella pneumoniae, Pseudomonas aeruginosa, Proteus mirabilis**, *Serratia marcescens** and *Enterobacter* species. **Skin and Skin-Structure Infections,** including those associated with postoperative wounds, ulcers and burns caused by *Escherichia coli, Proteus mirabilis, Serratia marcescens, Enterobacter* species, *Pseudomonas aeruginosa, Klebsiella pneumoniae,* and *Citrobacter* species*. **Intra-abdominal Infections,** including peritonitis caused by *Escherichia coli, Klebsiella* species, including *K. pneumoniae, Enterobacter* species including *E. cloacae**, *Pseudomonas aeruginosa, Citrobacter* species* including *C. freundii** and *Serratia* species* including *S. marcescens**. **Gynecologic Infections,** including endometritis and pelvic cellulitis caused by *Escherichia coli, Klebsiella pneumoniae**, *Enterobacter* species* including *E. cloacae**, and *Proteus mirabilis**.

AZACTAM is indicated for adjunctive therapy to surgery in the management of infections caused by susceptible organisms, including abscesses, infections complicating hollow viscus perforations, cutaneous infections and infections of serous surfaces. AZACTAM is effective against most of the commonly encountered gram-negative aerobic pathogens seen in general surgery.

Concurrent Therapy—Concurrent initial therapy with other antimicrobial agents and AZACTAM is recommended before the causative organism(s) is known in seriously ill patients who are also at risk of having an infection due to gram-positive aerobic pathogens. If anaerobic organisms are also suspected, therapy should be initiated using an antianaerobic agent concurrently with AZACTAM. Certain antibiotics (e.g., cefoxitin, imipenem) may induce high levels of beta-lactamase *in vitro* in some gram-negative aerobes such as *Enterobacter* and *Pseudomonas* species, resulting in antagonism to many beta-lactam antibiotics including aztreonam. These *in vitro* findings suggest that such beta-lactamase inducing antibiotics not be used concurrently with aztreonam. Following identification and susceptibility testing, appropriate antibiotic therapy should be continued.

CONTRAINDICATION—Aztreonam is contraindicated in patients with known allergy to this antibiotic.

WARNINGS—Careful inquiry should be made for a history of hypersensitivity reaction to any antibiotic or other drugs. Antibiotics should be given with caution to any patient who has had some form of allergy, particularly to drugs. It is recommended that patients who have had immediate hypersensitivity reactions (e.g., anaphylactic or urticarial) to penicillins and/or cephalosporins should be followed with special care. If an allergic reaction to aztreonam occurs, discontinue the drug and institute supportive treatment as appropriate (e.g., maintenance of ventilation, pressor amines, antihistamines, corticosteroids). Serious hypersensitivity reactions may require epinephrine and other emergency measures.

PRECAUTIONS—General: In patients with impaired hepatic or renal function, appropriate monitoring is recommended during therapy. If an aminoglycoside is used concurrently with aztreonam, especially if high dosages of the former are used or if therapy is prolonged, renal function should be monitored because of the potential nephrotoxicity and ototoxicity of aminoglycoside antibiotics. The use of antibiotics may promote the overgrowth of nonsusceptible organisms, including gram-positive organisms and fungi. Should superinfection occur during therapy, appropriate measures should be taken.

Carcinogenesis, Mutagenesis, Impairment of Fertility—Carcinogenicity studies in animals have not been performed. Genetic toxicology studies performed *in vivo* and *in vitro* with aztreonam in several standard laboratory models revealed no evidence of mutagenic potential at the chromosomal or gene level. Two-generation reproduction studies in rats at daily doses up to 20 times the maximum recommended human dose, prior to and during gestation and lactation, revealed no evidence of impaired fertility. There was a slightly reduced survival rate during the lactation period in the offspring of rats that received the highest dosage, but not in offspring of rats that received five times the maximum recommended human dose.

Pregnancy—Pregnancy Category B: Aztreonam crosses the placenta and enters the fetal circulation. Studies in pregnant rats and rabbits, with daily doses up to 15 and 5 times, respectively, the maximum recommended human dose, revealed no evidence of embryo- or fetotoxicity or teratogenicity. No drug induced changes were seen in any of the maternal, fetal or neonatal parameters that were monitored in rats receiving 15 times the maximum recommended human dose of aztreonam during late gestation and lactation. There are no adequate and well-controlled studies in pregnant women. Because animal reproduction studies are not always predictive of human response, aztreonam should be used during pregnancy only if clearly needed.

Nursing Mothers—Aztreonam is excreted in breast milk in concentrations that are less than 1% of concentrations determined in simultaneously obtained maternal serum; consideration should be given to temporary discontinuation of nursing and use of formula feedings.

Pediatric Use—Safety and effectiveness have not been established in infants and children.

ADVERSE REACTIONS—Local reactions such as phlebitis/thrombophlebitis following IV administration, and discomfort/swelling at the injection site following IM administration occurred at rates of approximately 1.9% and 2.4%, respectively. Systemic reactions (considered to be related to therapy or of uncertain etiology) occurring at an incidence of 1 to 1.3% include diarrhea, nausea and/or vomiting, and rash. Reactions occurring at an incidence of less than 1% are listed within each body system in order of decreasing severity: *Hypersensitivity*—anaphylaxis. *Hematologic*—pancytopenia, neutropenia, thrombocytopenia, anemia, leukocytosis, thrombocytosis. *Gastrointestinal*— abdominal cramps; rare cases of *C. difficile*-associated diarrhea or gastrointestinal bleeding have been reported. *Dermatologic*—purpura, erythema multiforme, urticaria, exfoliative dermatitis, petechiae, pruritus, diaphoresis. *Cardiovascular*— hypotension, transient ECG changes (ventricular bigeminy and PVC). *Respiratory*—one patient experienced flushing, chest pain, and dyspnea. *Hepatobiliary*—hepatitis, jaundice. *Nervous System*—seizure, confusion, vertigo, paresthesia, insomnia, dizziness. *Musculoskeletal*—muscular aches. *Special Senses*—tinnitus, diplopia, mouth ulcer, altered taste, numb tongue, sneezing and nasal congestion, halitosis. *Other*—vaginal candidiasis, vaginitis, breast tenderness. *Body as a Whole*—weakness, headache, fever, malaise.

Adverse Laboratory Changes—Those reported without regard to drug relationship during clinical trials were: *Hepatic*—elevations of AST (SGOT), ALT (SGPT), and alkaline phosphatase; signs or symptoms of hepatobiliary dysfunction occurred in less than 1% of recipients (see above). *Hemic*—increases in prothrombin and partial thromboplastin times, eosinophilia, positive Coombs test. *Renal*—increases in serum creatinine.

OVERDOSAGE—If necessary, aztreonam may be cleared from the serum by hemodialysis and/or peritoneal dialysis.

DOSAGE AND ADMINISTRATION—Dosage adjustments are recommended for patients with impaired renal function. In elderly patients, estimates of creatinine clearance should be obtained and appropriate dosage modifications made if necessary.

HOW SUPPLIED—AZACTAM For Injection (Aztreonam For Injection)—Lyophilized—is supplied in single-dose 15 mL vials containing **500 mg,** or **1 g**/vial; in single-dose 30 mL vials containing **2 g**/vial; and in single-dose 100 mL intravenous infusion bottles containing **500 mg** or **1 g** or **2 g**/bottle.

Consult package insert before prescribing AZACTAM (aztreonam).

Squamous Cell Carcinoma Arising in Previously Burned or Irradiated Skin

Michael J. Edwards, MD; Rose M. Hirsch, MD; J. Ralph Broadwater, MD; David T. Netscher, MD; Frederick C. Ames, MD

• Squamous cell carcinoma (SCC) arising in previously burned or irradiated skin was reviewed in 66 patients treated between 1944 and 1986. Healing of the initial injury was complicated in 70% of patients. Mean interval from initial injury to diagnosis of SCC was 37 years. The overwhelming majority of patients presented with a chronic intractable ulcer in previously injured skin. The regional relapse rate after surgical excision was very high, 58% of all patients. Predominant patterns of recurrence were in local skin and regional lymph nodes (93% of recurrences). Survival rates at 5, 10, and 20 years were 52%, 34%, and 23%, respectively. Five-year survival rates in previously burned and irradiated patients were not significantly different (53% and 50%, respectively). This review, one of the largest reported series, better defines SCC arising in previously burned or irradiated skin as a locally aggressive disease that is distinct from SCC arising in sunlight-damaged skin. An increased awareness of the significance of chronic ulceration in scar tissue may allow earlier diagnosis. Regional disease control and survival depend on surgical resection of all known disease and may require radical lymph node dissection or amputation.

(*Arch Surg* 1989;124:115-117)

Squamous cell carcinoma (SCC) arising in previously injured skin (Marjolin's ulcer) is a rare entity. We reviewed two subsets of patients with Marjolin's ulcers, those having previously burned skin and those having previously irradiated skin as the site of malignant transformation. The natural history, patterns of recurrence, and survival were analyzed for both groups. We hypothesized that injured skin, complicated by chronic ulceration, undergoes malignant transformation, and that the natural histories of the resulting carcinomas are similar and independent of the initial injury. We also compared these patients with a published analysis of all patients with SCC of the skin treated in our institution to determine whether patients with scar carcinomas had a poorer prognosis than patients with SCC arising in sunlight-damaged skin.

PATIENTS AND METHODS

The medical records of all patients treated at the M. D. Anderson Cancer Center, Houston, for SCC arising in previously burned or irradiated skin were reviewed. Records of 66 patients treated between 1944 and 1986 were analyzed for demographic data, clinical presentation, treatment, patterns of treatment failure, and survival.

Demographic data analyzed included age, gender, and factors related to the initial cutaneous injury. Factors believed to be important included age at the time of injury, cause and anatomic site of injury, wound treatment, time required for wound healing, and epithelial ulceration after initial healing.

Data analyzed relating to the clinical presentation of SCC included presenting signs and symptoms, stage of disease, and interval from the time of initial injury to the development of SCC. The extent of surgical procedures required for local disease control and the use of other treatment modalities were included in the analysis. Subsequent recurrence was analyzed by site (local skin, regional nodes, and distant metastasis) and time from surgical excision to recurrence. Differences between groups were analyzed using the two-sample t test and the χ^2 test where appropriate. Survival analysis was by the Kaplan-Meier method. Differences in survival rates were analyzed by the Wilcoxon test.

RESULTS

Twenty patients developed radiation-induced SCC and 46 patients developed squamous carcinoma after a thermal injury. At the time of diagnosis, the average age of all patients was 58 years; the majority (38 [58%]) were men. Mean age at the time of initial injury was 37 years in patients with radiation-induced injury and only 13 years in patients with thermal injury ($P<.01$).

The wounds in both groups were often (36 [55%]) allowed to heal by secondary intention. However, for 24 patients (36%), we found no clear record of initial wound management. The majority of patients (47 [71%]) experienced recurrent ulceration or prolonged wound healing. Only eight patients (12%) had primary wound healing without complications. The presence or absence of complications during healing could not be determined for 11 patients (17%).

The mean interval from initial injury to diagnosis of SCC was 37 years (range, 1.5 to 82 years). Squamous cell carcinoma developed earlier in irradiated skin than in burned skin (24.8 ± 15.7 compared with 43.7 ± 20.4 years, $P<.01$). During the last two decades, the incidence of both burn- and radiation-induced carcinomas decreased. At the time of diagnosis of carcinoma, most patients complained of a chronic fissure or ulcer for several months or years (Table 1). Presenting signs and symptoms were similar for irradiated and burned patients except that a greater number of burned patients presented with suspicious regional adenopathy (37% vs 5% [17 vs one]).

The head and neck and upper extremity were the most commonly involved anatomic sites. The hand was the most frequently involved site in patients who had radiation-induced cancers. Most carcinomas developed in sites considered to be predisposed to repeated trauma: the flexor (16 [34%]) and extensor (eight [17%]) surfaces over joints and areas overlying bony prominences (nine [19%]).

Initial surgical treatment was determined by extent of disease at presentation. Forty-two patients were initially treated with wide local excision alone. However, many patients required extensive resection to achieve adequate surgical margins. Eight had wide local excision and regional lymphadenopathy. Regional lymph nodes were dissected for patients presenting with suspicious adenopathy and for lesions directly overlying regional nodal basins. Prophylactic node dissection was not generally done. A major extremity amputation was required as initial treatment in seven patients. Locally advanced unresectable disease was treated by arterial chemotherapy (four patients) and radiation therapy (one patient). Systemic chemotherapy was used as initial therapy in one patient with metastatic disease. No treatment was given to one patient with extensive local and metastatic disease. The initial treatment of three patients at other institutions could not be determined.

Table 1.—Presenting Signs and Symptoms of 66 Patients

Complaint	No. (%) of Irradiated Patients	No. (%) of Patients With Burns	Total No. (%)
Chronic ulceration/fissure	20 (100)	45 (96)	**65** (98)
Pain	13 (65)	22 (48)	**35** (54)
Chronic infection	5 (25)	19 (40)	**24** (36)
Adenopathy	1 (5)	17 (37)	**18** (27)
Distant metastasis	0 (0)	3 (6)	**3** (5)

Table 2.—Sites of Initial Recurrence of Squamous Cell Carcinoma

Site	No. (%) of Irradiated Patients	No. (%) of Patients With Burns	Total No. (%)
Local skin	6 (30)	17 (37)	**23** (35)
Regional nodes	7 (35)	5 (11)	**12** (18)
Distant metastasis	1 (5)	2 (4)	**3** (5)
Total	**14 (70)**	**24 (52)**	**38 (58)**

Fig 1.—Survival rates of previously burned and irradiated patients ($P = .99$, Wilcoxon test).

Recurrent disease developed in 58% (38) of all patients. Of 42 patients who presented with apparent local disease, five (12%) subsequently developed regional nodal metastasis as their initial site of recurrence. The incidence of recurrent disease was higher for SCCs arising in irradiated skin (14 [70%]) compared with those arising in previously burned skin (24 [52%]). The time from the surgical treatment of cancer to recurrence ranged from two months to 28 years (median, 13 months for each subset). Most recurrences were in local skin and regional lymph nodes (Table 2). Median survival after local or regional recurrence was 21 and 12 months, respectively. Distant metastases eventually occurred in only 17% of patients (11) and were most often found in bone, followed by lung and distant skin.

Survival rates for all patients at 5, 10, and 20 years after their initial diagnosis of carcinoma were 52%, 34%, 23%,

Fig 2.—Recurrence rates and locations are compared between those of 1224 patients with squamous cell carcinoma of all types (106 recurrences, 8.7%) and 66 patients with previously irradiated or burned skin (38 recurrences, 58%).

respectively. Five-year survival rates were similar for both groups of patients: 53% at five years when carcinoma originated in previously burned skin and 50% where previously irradiated skin was the source ($P = .99$, Fig 1). Patients presenting with regional adenopathy had a particularly poor prognosis. Their median survival was 16 months; patients who had no adenopathy had a median survival of 66 months.

COMMENT

This review shows that patients with SCC arising in previously burned or irradiated skin have similar natural histories and survival. The age at initial injury was significantly lower for patients who were burned. The frequency of burns occurring in children and the older age at which patients or medical personnel usually received radiation therapy or exposure are the most likely reasons for this age difference.

The incidence of SCC arising from both irradiated and burned skin has declined over the past two decades. All patients in our series who had radiation-induced carcinoma were treated before 1959. Many of the radiation-induced upper-extremity and hand burns (nine patients [45%]) were the result of cutaneous injuries incurred by physicians and other medical personnel using now-outmoded radiation oncology or diagnostic radiologic equipment. Improvements in radiation technology and an improved understanding of radiation risks have made treatment safer and practically eliminated the risk of radiation-induced carcinoma.[1] The declining incidence of carcinomas arising in burned skin may be due to early, complete, and durable coverage of wounds. Improved methods of wound closure promote primary wound healing and reduce chronic wound problems that may predispose to malignant change.

These SCCs most frequently originate in areas of exposed skin most susceptible to burn or radiation injury: the head, neck, and extremities.[2] Repeated ulceration and prolonged healing of severe burn wounds have been noted as potential risk factors for the development of invasive carcinoma.[3] Wound sites where repeated trauma occurs are prone to chronic ulceration and potentially increase the risk of malignant transformation. In this series, 70% (33 patients) of cancers originated in scars over joints or bony prominences, which are sites susceptible to repeated trauma. The potential for chronic ulceration and delayed wound healing as risk factors for malignant transformation, especially in these areas prone to trauma, should be considered during initial wound management; complete wound healing should be achieved in these areas.

Ulcers and fissures that arise in areas of scarring that

fail to respond promptly to therapeutic measures should have biopsy specimens taken. A malignant lesion may appear as a benign chronic ulcer or fissure and be neglected for a long time. The patient often does not consult a physician until late in the course of the disease. Even then, many physicians may not recognize the significance of ulceration, which is why diagnosis late in the natural history of the disease is common.

Surgical excision is the most effective treatment for scar carcinomas. Where technically feasible, the entire area of previously injured skin should be excised with the carcinoma since residual burned or irradiated skin may be the site of future recurrent disease. Whether prophylactic node dissection would be useful is speculative. Among the 42 patients in our series with local disease initially treated by wide local excision alone, only five (12%) developed subsequent nodal metastasis. Our policy is to follow up regional nodes closely in these patients with localized primary carcinomas. We do not recommend routine prophylactic regional node dissection for localized scar carcinomas.

For patients who present with locally advanced disease and metastases to regional lymph nodes, extensive surgical procedures including regional lymph node dissection, extremity amputation, or resection of other vital tissues may be required.[4] Postoperative radiation therapy may be useful in previously burned patients with narrow surgical margins or nodal metastasis with extranodal extension into connective tissue.

Our high rate of overall recurrence (58% of all patients) is consistent with other reports but also may reflect a selection bias caused by the referral of patients with more advanced disease to the M. D. Anderson Cancer Center. A comparison with a previously reported series of all patients with cutaneous SCCs treated at our institution[5] shows that the rate of recurrence in the subset of patients with scar carcinomas was notably higher (58% vs 9%). Patterns of recurrence, however, were similar, with very few of the patients developing distant metastasis as the initial site of recurrence (Fig 2). A comparative review of the timing of the failures revealed that though approximately two thirds (24 of 38) of recurrences developed within the first 36 months after diagnosis (median, 13 months), approximately one fourth (eight of 38) developed after five years. This is in contrast to the timing of recurrences seen in patients with squamous carcinoma arising in sunlight-damaged skin, where recurrences after five years were rare.[5]

This study confirms that scar carcinomas are aggressive. Five-year survival was only 52%. In comparison, patients with sunlight-induced SCCs have a five-year survival of 90%.[6] The exact reason for the poor prognosis in patients with Marjolin's ulcers is unknown. Theoretical explanations of this poor prognosis have included an inherent biologic aggressiveness of scar carcinomas and the possibility that areas of scarring provide an immunologically privileged site for tumor growth.[7] Advanced disease at the time of diagnosis may be the primary factor. Patients with scar carcinomas have a high incidence of nodal involvement at initial presentation (27%). In contrast, patients with SCC due to actinic injury infrequently have nodal involvement (0.5% to 3.3%).[8,9]

In this study, the biologic behavior of carcinomas arising in irradiated and burned skin was similar. The prolonged course and neglect of lesions arising in scarred skin may be the primary factor responsible for their advanced stage at initial presentation and ultimately poor prognosis.[10] Early recognition and biopsy may be the most important management principle.

The appropriate control of radiation exposure and the current treatment of thermal injuries will prevent the majority of these aggressive cancers. An awareness of the etiologic factors and aggressiveness of these infrequent cancers is necessary to diagnose them promptly and provide optimal treatment.

Discussion

Q I was unaware in the past of the higher incidence of lymph node metastases in irradiated scar recurrences or malignant neoplasms as opposed to the burned ones. Perhaps burned patients have had split-thickness skin grafts and do not have much dermis, whereas in irradiated patients the skin was full thickness, with dermis, which allowed for lymphatic spread to regional nodes. Have the authors given this some thought?

A We had a higher percentage of burned patients with lymph nodes at the initial presentation. Thirty-seven percent of the people who were burned had positive nodes when they presented, whereas people who were irradiated had a much lower incidence of positive nodes. I do not know if this relates to the primary biology of the disease. However, the nodes were more likely to be dissected in the patients who were previously burned, and therefore, when disease recurred, it tended to recur not at the site of the regional nodes but in the local skin. People who were irradiated, on the other hand, did not as often have palpable nodes at initial presentation, and subsequently developed recurrences in the local nodes that had not been dissected. The radiation-induced carcinomas also tended to recur a bit earlier than the burn scar carcinomas.

Q As a radiotherapist, I can assure you that radiation fibroses lymphatics and markedly impairs the lymphatic drainage in that part, and this might explain why patients with radiation burns did not have such a high incidence of lymph nodal metastases.

Q I thought you said that about 17% of your entire series had distant disease. What did these patients die of?

A The vast majority died of an extensive tumor burden and complications related to locally advanced disease. Only 17% of the patients developed distant metastases at any time during the course of the disease. These metastases tended to occur in bone and lung and a few in distant skin.

Q Many of the tumors were much larger than the squamous carcinomas that occur in sun-damaged skin. Did you look at size as possibly related to prognosis? Did you compare them with the subset of patients with sun-related SCCs larger than 2 cm, which I believe is also a relatively poor prognostic group?

A We compared for size of lesions arising in the burned scalp compared with carcinomas that occurred in the scalp due to other causes, and we found a similar survival.

Q Ryan and Krementz did some interesting work with injection of fluorouracil into such tumors as you described, with the idea that this might immunologically protect the patient, and they had some interesting results. We have tried that ourselves, in a small number of cases. What is your feeling about that?

A That has been tried in a small number of patients, and there have been some interesting anecdotal experiences. However, no convincing scientific data currently exist that would make us want to change from our present standard therapy of surgical excision.

Is Limb-Sparing Surgery Applicable to Neurogenic Sarcomas of the Extremities?

John S. Bolton, MD; Jean-Nicolas Vauthey, MD; Gist H. Farr, Jr, MD; Edward I. Sauter, MD; John C. Bowen III, MD; David G. Kline, MD

• The presentation, treatment, and outcome of 12 patients with high-grade neurogenic sarcoma (NS) of the extremity were compared with those of 21 patients with high-grade extremity soft-tissue sarcoma of nonneural origin in a retrospective study from January 1976 to January 1988. Pain and neurologic deficit were more common in the NS group. Limb-sparing surgery was carried out with equal frequency in both groups. Local recurrence was six times more frequent in the NS group at three-year follow-up (59% vs 10%). Width of resection margin was the dominant prognostic variable bearing on local control after limb-sparing surgery. Anatomic and functional constraints tended to limit resection margin in patients with NS arising from mixed motor-sensory or predominantly motor nerves.

(*Arch Surg* 1989;124:118-121)

Within the past decade, limb-sparing surgery has become the treatment of choice for most extremity soft-tissue sarcomas (STSs). A multidisciplinary approach to these lesions has evolved, combining a function-sparing resection with adjuvant irradiation and/or chemotherapy. Reports from multiple institutions using a variety of multidisciplinary approaches have documented limb salvage rates in excess of 90% in selected patients, with no significant adverse effects of limb-sparing surgery on local control, distant disease-free, and overall survival rates.[1-4]

These reported series have included a variety of histotypes of STS. Tumor grade, size, and location have been viewed as the important tumor-related prognostic variables predictive of local control with limb-sparing surgery, and histotype has been viewed as relatively unimportant. However, to our knowledge, no series has analyzed the various histotypes of STS in sufficient detail to determine whether histotype has a bearing on the outcome of limb-sparing surgery.

Neurogenic sarcoma (NS) of the extremity may present unique anatomic and functional problems to the surgeon attempting to carry out limb-sparing surgery, especially when the tumor arises from a mixed motor-sensory nerve and is of high grade. Because of the relative rarity of these lesions, previous reported series of NS have often included cases accumulated over a long period during which treatment approaches have varied considerably.[5] Other series have combined truncal and extremity lesions in their analysis and have not reported treatment results separately by grade, relationship of the tumor to nerve, width of the resection margin, or type of primary surgical treatment.[6,7]

Because of referral patterns to our institution, we see a relatively large number of NSs involving nerves of the extremity. For this reason, we reviewed our recent experience and analyzed our results with limb-sparing surgery in this group of patients as compared with our overall experience with limb-sparing surgery in patients with high-grade STS of the extremity.

PATIENTS AND METHODS

Records of patients treated at our institution between January 1976 and January 1988 for STSs of the upper and lower extremity were reviewed. For this study, "extremity" STS included any lesion for which amputation was a therapeutic alternative, so that lesions of the shoulder and pelvic girdle were included. Patients judged to have metastatic disease at presentation such that treatment was not of curative intent were excluded from further review. The remaining cases were subjected to histologic review by one of us (G.H.F.) without knowledge of the clinical outcome. Lesions classified as low-grade (grade 1) on histologic review were excluded from further study. Twelve cases of high-grade NS of the extremity were identified. Eleven of these cases exhibited characteristic histologic features of peripheral nerve sheath tumors and, in addition, had prominent areas of high-grade sarcoma. Tumors were so designated if mitoses were abundant (more than ten per ten high-power fields), cells showed marked pleomorphism of nuclei and marked variation of nuclear/cytoplasmic ratios, and there were areas of necrosis. Areas were also seen in which the mitotic activity was high and tumor cells were small and uniform with little cytoplasm. These areas of primitive or undifferentiated sarcoma were used as additional evidence of highly aggressive tumors but were not used to make the diagnosis of NS per se. Heterotopic elements or epithelioid differentiation were occasionally seen. Seven patients had a well-established diagnosis of von Recklinghausen's disease. In all but one case of NS, the microscopic features were reinforced by a clear-cut origin of the tumor from a major nerve. The one exception was believed unequivocably to be an NS by virtue of histologic criteria alone. In addition, one

Table 1.—Patient and Tumor Characteristics at Presentation

	Neurogenic Sarcoma (N=12)	Soft-Tissue Sarcoma (N=21)	P*
Pain, No. (%)	12 (100)	2 (10)	<.01
Neurologic deficit, No. (%)	7 (58)	1 (5)	<.01
Associated von Recklinghausen's disease, No. (%)	7 (58)	0 (0)	<.01
Recurrent tumor at presentation, No. (%)	0 (0)	5 (24)	NS
Tumor size (mean), cm	9.3	9.2	NS
Tumor grade 3, No. (%)	10 (83)	17 (81)	NS
Proximal extremity location, No. (%)	10 (83)	16 (76)	NS
Below fascia, No. (%)	11 (92)	18 (86)	NS

*NS indicates not significant.

case of neuroepithelioma arising in the posterior tibial nerve was identified and included in the review. Cases identified as STS other than NS were classified and graded according to standard histopathologic criteria.

Thus, initial clinical and histologic review identified 12 patients with high-grade extremity NS and 21 patients with high-grade extremity STS (other than NS) treated with curative intent. These cases underwent intensive clinical review, and the following information was collected: size, grade (2 or 3), and location of the lesion within the extremity; presenting symptoms and signs, including the presence or absence of pain and neurologic deficit; functional status before and after treatment; type of resection employed, with particular attention to the gross and microscopic margins; type of adjuvant treatment; and the local disease-free, distant disease-free, and overall survival.

Follow-up was obtained by patient examination in most instances. When this proved impossible, follow-up was obtained by telephone contact with the local physician or directly with the patient. Median follow-up for survivors was 26 months. Local and distant disease-free survival curves and overall survival curves were generated by life-table analysis. Comparisons between survival curves were done by the Breslow test (generalized Wilcoxon statistic),[8] and a multivariate analysis of factors that significantly affected local recurrence was performed by means of the Cox proportional hazards regression model.[9] Additional comparisons between groups was done by χ^2 analysis.

RESULTS

Of the 12 patients identified with high-grade NS of the extremity, in ten the NS arose from a mixed motor-sensory nerve. The nerves of origin were as follows.

Nerve	No.
Brachial plexus element	5
Sciatic	1
Posterior tibial	1
Ulnar	1
Median	1
Obturator	1

The 21 patients in the STS group had a variety of histotypes, as follows.

Histotype	No.
Neurogenic sarcoma	12
Malignant fibrous histiocytoma	8
Leiomyosarcoma	2
Synovial sarcoma	2
Liposarcoma	2
Epithelioid sarcoma	2
Malignant mesenchymoma	2
Malignant giant-cell tumor	2
Rhabdomyosarcoma	1

Table 1 details the clinical features of each group. Significant differences were apparent in the presence of pain, neurologic deficit, and association with von Recklinghausen's disease, all of which were more common in the NS group. However, the two patient groups were similar in regard to tumor size, percentage of grade 3 lesions, frequency of proximal and deep (below fascia) location, and presence of recurrent disease on presentation for treatment at our institution. Median patient age was 37 years for the NS group and 66 years for the STS group.

Table 2.—Treatment Characteristics

	No. (%)		
	Neurogenic Sarcoma (N=12)	Soft-Tissue Sarcoma (N=21)	P*
Primary amputation	3 (25)	2 (9.5)	NS
Limb-sparing resection	9 (75)	19 (90.5)	NS
<1-cm margin	7 (78)	8 (42)	NS
>1-cm margin	2 (22)	11 (58)	NS
Adjuvant radiation therapy	5 (56)	11 (58)	NS
Adjuvant chemotherapy	3 (33)	8 (42)	NS

*NS indicates not significant.

All patients in this series underwent an attempt at definitive resection with curative intent. Table 2 details the surgical and adjuvant treatment given in each group. The primary amputation rate was slightly higher in the NS group, but this difference was not significant. Amputation achieved an adequate margin (minimum of 1 cm) in all cases in which it was employed. Among the patients treated with limb-sparing surgery, a higher proportion of patients with NS had less than a 1-cm margin; however, this difference was not significant. Adjuvant radiation therapy and chemotherapy were used with equal frequency in each group.

Local disease-free survival at 36 months was 41% for the NS group and 90% for the STS group (Fig 1). This difference was significant ($P<.03$). Distant disease-free survival and overall survival rates were not significantly different between the two groups; however, the trend clearly favored the STS group, and the difference approached significance for overall survival (Fig 2). For the 33 patients as a whole, margin width was examined as a prognostic factor predictive of local disease-free survival. A highly statistical significant advantage in favor of the group having margin width greater than 1 cm was demonstrated ($P=.009$; Fig 3). Cox regression analysis was used to compare the relative contribution of the histotype (NS vs all other) and the margin width in determining the local disease-free survival. Both variables contributed significantly ($P=.024$

Fig 1.—Local disease-free survival in neurogenic sarcoma (dashed line) and soft-tissue sarcoma (solid line) groups.

Fig 2.—Overall survival in neurogenic sarcoma (dashed line) and soft-tissue sarcoma (solid line) groups.

Fig 3.—Local disease-free survival as function of resection margin width greater than 1 cm (solid line) or less than 1 cm (dashed line).

and $P=.005$, respectively); however, margin width appeared to be the dominant variable in predicting local disease-free survival. The significance of the combination was $P=.0016$.

Although the primary amputation rate was only slightly higher for the NS group, the ultimate amputation rate was significantly higher in that five patients in the NS group required amputation for recurrent disease, while only one patient in the STS group did so. Only two of 12 patients in the NS group retained an anatomically and functionally intact extremity until death or termination of the study as compared with 16 of 21 patients in the STS group ($\chi^2=4.96$, $P<.05$).

COMMENT

This study demonstrated that patients with high-grade NS of the extremity had a significantly higher risk of local recurrence after limb-sparing surgery than did patients with high-grade STS of other histologic type. While significant differences in distant disease-free survival and overall survival were not manifest between these two groups, the strong trend toward decreased overall survival in the NS group suggests that this difference will become significant with longer follow-up or with larger sample size.

In our NS group, the tumor arose from a mixed motor-sensory nerve of the extremity in ten of 12 patients. The two patients whose tumor did not arise from such a nerve had favorable outcomes in regard to local and distant disease-free status and functional result, suggesting that the adverse outcome noted in this study is largely confined to the group with involvement of mixed motor-sensory nerve. Thus, the results of this study cannot be extrapolated to NSs of the extremity that are of low grade or that do not involve mixed motor-sensory nerves. In our overall institutional experience (data not shown), management of these latter groups has not posed difficulties greater than those seen with STS in general.

With covariate analysis, the width of resection margin emerged as the dominant variable predictive of local disease-free survival. Anatomic and functional constraints tended to limit margin width in the NS group, as less than total nerve ablation was done in the majority of cases in the hope of preserving nerve function. Thus, although all gross tumor was thought to have been removed by the operating surgeon, microscopic, and in some cases even a small amount of macroscopic, disease may have persisted. Others have noted the importance of adequate margin in limb-sparing surgery for extremity STS,[10,11] and recurrence after inadequate resection is not unique to patients with NS. When the NS involves mixed motor-sensory nerves, however, the extent of functional loss encountered in adequate resection is extensive. Thus, the problems posed by NS of the extremity relate more to functional and anatomic considerations that bear on margin size with limb-sparing surgery than to any different biologic behavior per se of these lesions.

The 36% incidence of NS among our overall group of patients with high-grade extremity STS was higher than that reported in most series, but this is explained by referral patterns to one surgeon at our institution (D.G.K.), not by the histologic criteria used to diagnose NS in this study.

In a recent review of localized STS of the lower extremity, Collin et al[12] noted neurofibrosarcomas to have a significantly higher risk of local recurrence than did other histotypes of STS. This analysis included grade 1 lesions; moreover, the histologic criteria for diagnosis of neurofibrosarcoma and the relationships of the tumors to motor

nerve were not detailed in this study. Therefore, no direct comparison can be drawn between our study and that of Collin et al; however, it is likely that an even higher local recurrence rate would have been noted in the earlier study had attention been focused on high-grade tumors involving major nerves.

Despite the findings of this study, it is possible that a significant proportion of patients with NS of the extremity can undergo limb-sparing surgery. However, the provision of adequate proximal, distal, and radial margins remains the paramount consideration bearing on local control of tumor with limb-sparing surgery, since, in this study as in others, adjuvant therapy could not ensure local control if the initial surgical margin was inadequate.[13,14] Thus, for high-grade NS involving motor nerve, segmental nerve resection will be required in virtually every case along with wide radial resection. When this can be accomplished with anticipation of acceptable extremity function postoperatively, limb-sparing surgery should be carried out in preference to amputation. Nambisan et al,[7] for example, reported sciatic nerve sacrifice as an adjunct to limb-sparing surgery for an NS involving the sciatic nerve, resulting in moderate functional impairment but with an overall acceptable functional result.

By contrast, high-grade NSs arising from the brachial plexus are especially difficult to control with limb-sparing surgery, because adequate longitudinal and radial resection entails sacrifice of a large portion of the innervation of the upper extremity and possibly the axillary artery and vein. The current study included five patients with high-grade NS of the brachial plexus. In each of these cases, the tumor was located at or distal to the cord level, such that interscapulothoracic amputation could have achieved an adequate proximal margin. Three patients who were initially treated with limb-sparing resection and adjuvant chemoradiotherapy rapidly had recurrences. In each case, only a limited initial resection was done in an attempt to preserve neurologic function. The two remaining cases were initially managed with interscapulothoracic amputation and remain free of disease, with good functional status, at 21 and 24 months.

Neurogenic sarcomas involving the brachial plexus at the root or truncal level are not included in this review. For lesions at this level, neither wide local resection nor interscapulothoracic amputation proximal to the tumor is possible. Only subtotal resection followed by irradiation and/or chemotherapy is possible in these cases.[15]

Discussion

Q Did you break down your analysis by tumors arising from the plexus vs peripheral nerves, and was there any difference in recurrence rates?

A We had five patients with brachial plexus tumors; two of them were treated with primary amputation and they had no recurrence; three patients had an attempt at limb-sparing surgery with inadequate primary resection; they had recurrences and eventually died.

Q I think your conclusions are essentially correct. However, I think that because of the numbers of the patients, it is hard to draw detailed conclusions. In general, if only one nerve of the extremity can be resected, this is preferable to an amputation. This includes the sciatic nerve. In other words, if one has to resect the sciatic nerve because of tumor involvement, the result is far superior to an amputation. If you're dealing with the brachial plexus, then it is altogether a different situation. The other point is, as true of other STSs, postoperative radiation is helpful to provide local control if you have removed all the gross tumor, but the surgical margin may be inadequate.

Q What I am interested in is whether you think that the radiation therapy that was used was adequate or if you might have had better results with the limb-sparing surgery. In the original abstract, for instance, some of the patients didn't receive radiation therapy as an adjuvant at all.

A I think the message is to obtain adequate margins in all cases. You can see that we obtained good results in nonneurogenic STSs with 90% local disease-free survival, and this compares well with other series. During the same period we made the same progress in high-grade NSs arising from major motor nerves. Radiation therapy was used mainly as an adjuvant, and with a small number of patients. I don't think that we can draw a conclusion. I don't think radiation therapy can make up for positive margins.

Patterns of Recurrence After Resection of Osteosarcoma of the Extremity

Strategies for Treatment of Metastases

James F. Huth, MD, Frederick R. Eilber, MD

• We studied recurrence patterns in 255 patients with high-grade osteosarcoma of the extremity and the efficacy of the treatment of these recurrences. One hundred seven patients developed metastatic disease: 77 had isolated pulmonary metastases, 17 had simultaneous metastases to lung and elsewhere, and 13 had metastases to other sites. Of the 77 patients with metastases confined to the lung, 51 (66%) underwent thoracotomy for resection of the metastases, and 13 (17%) are long-term disease-free survivors. Patients with simultaneous metastases to lung and other sites, and patients with metastases to sites other than lung, have a poor prognosis with only one long-term disease-free survivor in these groups. Thoracotomy has a limited role in the treatment of metastatic disease. Improvements in aggressive, systemic chemotherapy are essential for improving the prognosis in these patients.

(*Arch Surg* 1989;124:122-126)

Osteosarcoma is a relatively uncommon malignant neoplasm that commonly affects individuals in the second decade of life. The majority of these tumors involve the long bones of the extremity that are the most actively growing areas of bone at this stage of life. These tumors have a propensity for local recurrence, as well as hematogenous spread. Metastases to the regional lymph nodes are uncommon. Pulmonary metastases are the most common initial manifestation of disseminated disease.

At the time of diagnosis, most patients with osteosarcoma of the extremity do not have detectable distant metastatic disease. Until recently, therapy was directed toward removal of the primary lesion, usually by means of an amputation.[1] Most patients went on to develop metastatic disease and eventually died of uncontrolled disseminated disease.[2] Recent advances in multimodality treatment of osteosarcoma have resulted in (1) better local control with a significant decrease in the rate of local recurrence and (2) improvement in overall survival.[3-5]

We have treated 162 patients with high-grade osteosarcoma of the extremity from 1974 through 1986. Our study examines the patterns of recurrence in these patients and the efficacy of the various treatment modalities used to treat metastatic disease to various sites.

PATIENTS AND METHODS

Eligibility Criteria

One hundred sixty-two patients with a diagnosis of high-grade osteosarcoma of the extremity seen in the division of surgical oncology from 1974 through 1986 were included in this study. The criteria for inclusion were as follows:

1. The tumor was localized to the primary site (femur, tibia, fibula, humerus, radius, or ulna) with no evidence of metastatic disease. Preoperative workup included a complete physical examination, blood chemistry determinations, chest roentgenogram, computed tomographic (CT) scan of the lung or whole-lung tomography, CT scan of the primary site to assess the extent of the tumor, and bone scan.
2. Preoperative confirmation that the tumor was high grade (Enneking stage II)[6] was made by the Pathology Department at UCLA.
3. After giving informed consent, all patients underwent resection of the tumor at our institution. An attempt was made to perform an en bloc excision of the tumor and involved bone with at least an 8-cm proximal margin (from the most proximal area of bone marrow involvement) and reconstruction of the excised segment with allograft or endoprosthesis. An amputation was performed when ability to achieve a satisfactory margin was not possible or when the patient did not desire a limb-salvage procedure.

Preoperative Therapy

Chemotherapy.—Preoperative chemotherapy was offered to all patients before surgery. Patients choosing the limb-salvage program were offered intra-arterial doxorubicin hydrochloride (Adriamycin) infusion. Intra-arterial catheters were placed percutaneously by the Seldinger technique under fluoroscopic guidance

Accepted for publication Sept 21, 1988.

in the department of radiology. Doxorubicin was given by continuous infusion at the rate of 30 mg/d for three days (total dose, 90 mg). Patients who refused intra-arterial therapy received preoperative intravenous chemotherapy (T-10 Rosen protocol).[7]

Radiotherapy.—Radiation therapy was given at 3.5 Gy fractions for five or ten days using a 10-meV linear accelerator to patients who received intra-arterial doxorubicin. The dosages were changed over time to maximize the therapeutic advantage while minimizing local complications of this therapy.

Surgery

We attempted an en bloc excision of the primary tumor with an 8-cm proximal margin and confirmation that other margins were also free of tumor at the time of excision in each case. Reconstruction was achieved with either a cadaveric allograft or a custom-designed metallic endoprosthesis. Amputation was performed when a functional reconstruction was not feasible or when the patient refused a limb-salvage procedure.

Postoperative Therapy

Beginning in 1978, patients were offered adjuvant chemotherapy as part of a prospective, randomized study comparing the T-10 Rosen protocol (doxorubicin, methotrexate sodium, vincristine sulfate, bleomycin sulfate, cyclophosphamide, dactinomycin) vs no therapy. Patients treated before this time received doxorubicin and high-dose methotrexate with leucovorin calcium rescue.

Patient Follow-up

Patients were examined one week and one month after discharge from the hospital, and then at three-month intervals. Follow-up examination included a physical examination, blood chemistry determinations, and chest roentgenogram. Lung tomography or chest CT scan was performed at six months. If recurrence was suspected, appropriate additional examinations were performed, and therapeutic options including chemotherapy, radiation therapy, or additional surgery were considered.

RESULTS

Patient Enrollment

One hundred sixty-two (105 male, 57 female) patients were included in this study. The patients ranged in age from 3 to 75 years (median, 20 years). The age and sex distribution is shown in Fig 1.

Fig 1.—Age and sex distribution of patients. There were 105 male patients and 57 female patients, ranging in age from 3 to 75 years. Median age was 20 years. Over 65% of patients were between ages of 11 and 20 years.

Site of Primary Tumor and Operation Performed

Primary Tumor Location	No. of Patients			
	Amputation	Excision and Cadaver Graft	Excision and Endoprosthesis	Other
Femur				
Distal	21	11	70	2
Proximal	1	1	9	0
Tibia	17	0	2	2
Fibula	2	0	0	1
Humerus	2	8	9	1
Radius	2	0	0	1
Total	**45**	**20**	**90**	**7**

Location and Histologic Findings

All tumors in this study arose in the long bones of the extremity. All tumors were high-grade osteosarcoma (Enneking stage II). The Table gives a complete listing of the location of the primary tumor and the operation performed to remove the tumor.

Preoperative Therapy

Ninety-one patients received preoperative intra-arterial doxorubicin followed by preoperative radiation therapy. Forty-five patients received 17.5 Gy, and 46 received 35 Gy of preoperative radiation. Forty-three patients received multimodality preoperative chemotherapy without radiation therapy. The remaining 28 patients, all of whom underwent extremity amputation, elected not to receive preoperative radiation therapy.

Surgical Procedures

Of the 134 patients receiving preoperative therapy, 117 were able to undergo limb-sparing surgery. As listed in the Table, these procedures included (1) replacement of the excised segment with a cadaveric allograft, 20 patients; (2) replacement of the excised segment with a custom-fit metallic endoprosthesis, 90 patients; and (3) other procedure (excision without reconstruction, excision and fusion), seven patients. The remaining 45 patients underwent amputation because they did not want a limb-salvage procedure (28 patients) or because of inability to perform an adequate excision and spare a functional extremity (18 patients).

Complications of Therapy

Fifty-eight postoperative complications occurred in 45 patients. Patients undergoing amputation had only three complications (6.6%), and all three were wound sloughs that required reoperation. Twenty-seven patients (30%) who underwent excision and reconstruction with an endoprosthesis had 33 postoperative complications, and 18 required further surgery, including three amputations. These complications included five wound sloughs, six infections, four loosenings, five fractures, four stiffnesses of the extremity, two nerve palsies, three positive operative margins, one extrusion of the prosthesis, one instability of the prosthesis, one phlebitis, and one flexion contracture. Fourteen patients (70%) who had an excision and cadaver allograft had 23 complications, all requiring reoperation. These included six loosenings, four extrusions, four fractures, two infections, one instability, one arterial thrombosis, and one positive surgical margin. Four of these patients required subsequent amputation. One hundred seventeen patients (72%) had no postoperative complications.

Postoperative Therapy

Fifty-one patients received a combination of doxorubicin and high-dose methotrexate postoperatively, 63 received the T-10 protocol as described by Rosen, ten received other

Fig 2.—Disease-free survival of all patients. One hundred seven patients (66%) developed recurrent disease. Actuarial disease-free survival was 48%, 35%, 31%, and 28% at 1, 2, 3, and 4 years, respectively, after original surgery.

Fig 4.—Site of primary tumor vs recurrence. Site of primary tumor (femur, tibia, or humerus) had no significant effect on incidence of metastatic disease.

Fig 3.—Procedure vs recurrence. Procedure performed on primary tumor had no significant effect on incidence of metastatic disease. CAD indicates cadaver.

Fig 5.—Procedure vs pattern of recurrence. Procedure performed on primary tumor had no significant effect on distribution of metastatic disease. CAD indicates cadaver.

doxorubicin-containing regimens, and 38 received no postoperative adjuvant chemotherapy.

Recurrence

One hundred seven (66%) of 162 patients developed recurrent disease during the follow-up period. Actuarial analysis of disease-free survival (DFS) is shown in Fig 2. Disease-free survival was 48%, 35%, 31%, and 28% at 1, 2, 3, and 4 years, respectively. Median time to recurrence was 12 months. Patients who received adjuvant chemotherapy had an improved DFS (median DFS, 14 months) compared with those who did not receive postoperative chemotherapy (median DFS, six months). There was no significant difference in survival between those who received doxorubicin–high-dose methotrexate vs those who received the T-10 protocol.

Patterns of Recurrence

The lung was the sole site of metastases in 77 (72%) of the 107 patients who developed recurrent disease. An additional 17 patients (16%) developed recurrent disease simultaneously in the lung and one additional site: six local, five bone, and six central nervous system. The remaining 13 patients (12%) had recurrence at isolated sites distant from the primary site: ten bone, two soft tissue, and one central nervous system.

Patients who underwent an amputation had a slightly higher incidence of recurrence (80%) compared with those undergoing limb-salvage surgery (60%), as shown in Fig 3. However, these differences were not statistically significant. Neither the location of the primary tumor (Fig 4) nor the procedure performed on the primary tumor (Fig 5) had any effect on the distribution of metastatic disease. The pattern of metastatic disease was similar for patients who received adjuvant chemotherapy compared with those who received no postoperative therapy.

Management of First Recurrence

Metastases Confined to the Lung.—Seventy-seven patients had lung metastases as the only manifestation of recurrence, and 51 (66.2%) of 77 were candidates for pulmonary resection based on the size and number of metastases as well as the interval of time from resection of the primary tumor to recurrence. Additional criteria for resectability included (1) no evidence of recurrent disease at the primary site, (2) no evidence of hilar disease on chest roentgenogram or lung CT scan, and (3) no pleural effusion. The median time to recurrence in those patients who underwent thoracotomy was nine months (range, one to 46 months) compared with a median of five months (range, one to 11 months) for those who did not undergo throacotomy.

Of the 77 patients with metastases isolated to the lung, 51 (66%) underwent thoracotomy. Forty-six (90%) of these 51 patients were able to have all their disease resected. This included 21 patients with bilateral disease and 25 patients with unilateral disease. Twelve patients remained free of disease after their first thoracotomy, nine of whom had unilateral disease, and three of whom had bilateral disease. (Patients with bilateral disease underwent median

Fig 6.—Survival of patients with metastases confined to lung. Seventy-seven patients had metastases confined to lung. Fifty-one underwent thoracotomy for resection of metastases, and 26 had no further surgery. Actuarial survival for patients who underwent thoracotomy was 71%, 45%, 36%, and 23% at 1, 2, 3, and 4 years, respectively, following *diagnosis* of recurrence.

sternotomy or staged thoracotomy, which for purposes of discussion is considered one operation for metastatic disease.) Survival for patients after thoracotomy was 71% at one year, 45% at two years, 36% at three years, and 23% at four years after diagnosis of recurrence (median survival, 20 months).

Of the 26 patients who were not considered candidates for resection of their pulmonary metastases, 24 died with a median survival of five months after diagnosis of their first recurrence (Fig 6).

Metastases to the Lung and Another Site.—Seventeen patients developed metastases to the lung and another site. Six developed a local recurrence in addition to pulmonary metastases, five developed simultaneous metastases to lung and bone, and six developed simultaneous metastases to lung and the brain. Despite attempts to control disease in this group (with 11 thoracotomies, one amputation, and two excisions), 16 died; the remaining patient is alive and free of disease 47 months after undergoing a thoracotomy and excision of a local recurrence. The median survival for this group is ten months.

Metastases to Sites Other Than the Lung.—Thirteen patients developed recurrent disease at a site other than the lung. Ten patients developed bony metastases, two developed a recurrence in soft tissue of the pelvis, and one developed a brain metastasis. Twelve died, and one remains alive 17 months after diagnosis of bone metastases receiving chemotherapy. Further surgery failed to permanently control disease in the four patients in whom it was attempted. The median survival for this group was nine months.

Management of Second Recurrence

Thirty-four patients had recurrence after thoracotomy for resection of isolated lung metastases. The site of recurrence was limited to the lung in 30, involved the lung and other sites in two, and involved bone and soft tissue in the remaining two. In all patients with extrapulmonary recurrences, disease was unresectable. The 30 patients with recurrent metastases confined to the lung represent 16 patients whose initial lung involvement was bilateral and 14 patients whose initial involvement was unilateral. Of the 14 patients whose previous pulmonary disease was unilateral, six had recurrence in the ipsilateral lung, four had recurrence in the contralateral lung, and four had recurrence in both the lung that was operated on and the lung that was not operated on. Twelve of the 30 patients underwent another thoracotomy.

Management of Third Recurrence

All 12 patients who underwent a second thoracotomy for metastatic disease had recurrence. All but one of these recurrences were confined to the lung. Seven patients underwent a third thoracotomy, and one patient remains free of disease 14 months after his most recent operation.

COMMENT

Our study was undertaken to examine the metastatic patterns in patients with osteosarcoma of the extremity and the role that surgery plays in the further management of patients in whom primary treatment fails. There have been several studies examining the role of thoracotomy in the treatment of metastatic disease.[8-10] These studies examined a highly select population of patients, many referred because they met certain criteria of resectability. Our study avoids this selection criteria, because we have included all patients with extremity osteosarcomas who have had all their initial treatment at our institution.

Metastatic disease in the lung accounted for the overwhelming majority of recurrences. The overall incidence of metastases to the lung was 94 (58%) of 162, which included 77 patients with metastases only to the lung and 17 patients with metastases to the lung and another site. This represents 88% (94/107) of all the metastatic disease encountered. Surgery only had an impact in patients with metastases confined solely to the lung: 13 (25%) of 51 patients undergoing thoracotomy are long-term, disease-free survivors. However, this represents only 17% (13/77) of all patients with metastases confined to the lung and only 12% (13/107) of all patients who developed metastatic disease. Thus, the impact of resection of pulmonary metastases on improving survival of patients with osteosarcoma is minimal.

The overall prognosis in the treatment of osteosarcoma appears to be improving because of the development of more rigorous and effective adjuvant chemotherapy programs. These programs have evolved to include preoperative neoadjuvant chemotherapy. The purpose of this therapy is twofold: (1) to begin systemic treatment earlier in the course of the disease without the two- to four-week delay required for surgery and subsequent postoperative recovery and (2) to examine the effect of the preoperative therapy on the primary tumor to better plan postoperative treatment. Rosen et al[7] have demonstrated that switching the therapy regimen postoperatively in patients who failed to show a good response to the preoperative regimen results in a better disease-free survival.

Although we believe that surgery still has a role in the treatment of metastatic disease, our study suggests that the impact of surgical resection is small, approximating a 10% improvement in overall survival. Because the lung is the primary site of initial recurrence, it is tempting to try to focus additional therapy at this site. At this point, however, the therapeutic options are limited. Zaharia et al[11] have described a series of patients treated with adjuvant radiation therapy to the lung parenchyma in conjunction with systemic chemotherapy after resection of the primary tumor. These patients received 20 Gy whole-lung irradiation postoperatively in an attempt to control micrometastases to the lung. All seven patients treated only with irradiation to the lung had recurrence in the lung, and 19 (65.5%) of 29 patients who received radiation and chemotherapy had recurrence. Thus, it would appear that radiation at this dosage is insufficient to control

pulmonary metastatic disease. Pulmonary tolerance to radiation therapy prohibits the use of higher doses of radiation. Future progress in the control of metastatic disease would appear to be dependent on further refinements in the use of preoperative and postoperative chemotherapy.

Discussion

Q The topic that has been of interest to many individuals and institutions through the years is the role of thoracotomy and resection of metastases, either osteosarcoma or other diseases. I am curious about whether or not you believe that you have identified any subgroup of patients that you would not take to surgery. What were the criteria of inoperability in the patients who never made it to surgery and on the patients who did undergo resection? Are there any that you would not do again? Do you still advise second and third operations for resection of metastases? Is there a number of metastases beyond which all patients had a recurrence?

A I think our indications for a thoracotomy have become more restrictive over the years and in this series we were certainly generous in our indications for a thoracotomy, as it dates back to 1974. We do have certain criteria. We like to see a disease-free interval of a year or a tumor doubling time of greater than 40 days, and certainly solitary vs multiple metastases have been shown in several series to do better, although it is not to the extent where you would exclude multiple metastases only on that basis. If patients present with a short disease-free interval or a rapid tumor doubling time, we tried to manipulate their chemotherapy to slow down the growth of the tumors before we subjected them to thoracotomy. We have ruled out for thoracotomy patients who present with a pleural effusion with malignant cells or patients who present with significant disease in the hilum. You can argue that the number of metastases makes a difference, but one patient stands out in my memory. He was a 20-year-old man who on CT scan appeared to have four metastases; at the time of exploration he had over 50. He had only one resection of these and has not had a recurrence after five years. The data also show that recurrent disease in the lung carries a very poor prognosis. Operating two or three times has diminishing returns, although the one patient who survived after three thoracotomies would probably disagree with me.

Q What have we accomplished when we fail? That is, in all of these patients who are heavily pretreated with "big-gun" chemotherapy or experimental agents, how much have you extended their life span for those who eventually die of their disease?

A That is a very difficult question to answer. Obviously, we select patients for thoracotomy now because they have a slow-growing tumor and a long disease-free interval. If you just set them aside and do not operate on them, they are going to have a better survival than those that you exclude from thoracotomy.

The bottom line, I guess, has to be how many patients undergo resection who never have a recurrence. I do not think this is at odds with previous data that we presented because those were selected patients and there were a lot of patients we treated who were sent in for a thoracotomy because they were at good risk. The percentages get better then; up to 40% of those patients are disease free, as opposed to 25%.

In this series, we have looked only at patients who came to us with their primary tumor intact, who were then operated on with no evidence of metastatic disease at that time and then were followed up through the course of their disease until they had a recurrence or not. So it is an unselected group and the statistics look worse.

Q In these young patients, it seems that basically each resection has provided about one year of palliation for very little morbidity and no operative mortality.

A Yes, I think we may be helping the young patient who will bounce back from the surgery very quickly. Even though he or she goes on to experience recurrence, I suspect we have prolonged his or her life. It is difficult to evaluate prolongation of life because we really have no basis for comparison since these patients are already highly selected.

The Pitfalls of Technetium Tc 99m/Thallium 201 Parathyroid Scanning

G. Scott Voorman, MD; George H. Petti, Jr, MD; Eloy Schulz, MD; George D. Chonkich MD; Gerald A. Kirk, MD

Technetium Tc 99m/thallium 201 parathyroid scanning has been proved to be effective by multiple researchers. A review of 54 patients who underwent scanning and operations at an institution showed the scans to be accurate in 83%. There were 15% false-negative and 2% false-positive scans. The pitfalls of parathyroid scanning can be related to false-positives and false-negatives (*Arch Otolaryngol Head Neck Surg* 1988;114:993-995).

Clinical Experience With Regional Pancreatectomy for Adenocarcinoma of the Pancreas

William F. Sindelar, MD, PhD

• Twenty patients with adenocarcinoma of the pancreas underwent a regional pancreatectomy, including resection of the pancreas, regional lymphadenectomy, duodenectomy, antrectomy, and sleeve resection of the portal vein. Three patients required mesenteric arterial reconstruction. Adjunctive radiotherapy was administered to 17 patients, with 11 patients receiving intraoperative radiation and six patients receiving postoperative external-beam–radiation. Complications developed in 11 patients (55%), including infectious and septic events (five patients), biliary or enteric fistulas (two patients), mesenteric vascular thrombosis (two patients), and other complications (two patients). Four patients (20%) suffered treatment-related deaths. The overall median survival was 12.0 months. Survival at one year was 50% and, at three years, 10%. Two patients died of causes unrelated to cancer at 18 and 39 months, and one patient remains alive and free of disease 50 months following therapy. Morbidity and survival did not differ among patients who received intraoperative, conventional postoperative, or no radiation therapy. Although occasional patients may benefit with survivals of longer than three years, regional pancreatectomy carries major morbidity and produces little survival benefit for most patients with pancreatic cancer.

(*Arch Surg* 1989;124:127-132)

Surgical resections for adenocarcinoma of the pancreas carry considerable mortality and morbidity and only rarely result in long-term survival.[1] Although resection is the only potentially curative treatment modality for pancreatic cancer, typically fewer than 10% of all patients with pancreatic adenocarcinoma have disease sufficiently localized to permit surgical extirpation.[1] Traditionally, pancreatduodenectomy (Whipple's operation) has been utilized to resect localized disease in patients, although some surgeons have advocated total pancreatectomy. However, with either pancreatduodenectomy or total pancreatectomy, less than 10% of patients have been long-term survivors, and at least 50% of patients have local recurrences within the resection bed.[1,2]

In attempts to extend the limits of resectability, to improve local control rates, and to improve survival, Fortner[3] developed the regional pancreatectomy, an extirpative procedure that removes en bloc the pancreas, regional lymph nodes, duodenum, gastric antrum, and intrapancreatic portal vein. The technically complex procedure was proposed as a method of surgically removing tissues in the region of pancreatic neoplasms to afford wide margins in all directions. The morbidity and mortality of the regional pancreatectomy in experienced hands were reported to be comparable with Whipple's resections or total pancreatectomies, and the procedure was suggested to improve survival.[4] A 62% one-year survival rate was achieved at Memorial Sloan-Kettering Cancer Center, New York, in 1977.[4] Fortner[5] reported a series of 61 patients in 1984, who had undergone regional pancreatic resections, with median survivals of 13 months for patients having pancreatic adenocarcinomas and 40 months for patients with periampullary or islet cell tumors of the pancreas.

Regional pancreatectomy has generated controversy among surgeons.[6] The procedure has been suggested by some to extend resectablity and to promote disease control, while others have criticized the operation as being highly morbid and technically difficult without a meaningful impact on overall survival. Relatively few institutions have performed the regional resection, and its use, at present, must be considered investigational.[1]

The present article describes the experience with regional pancreatic resections performed at the National Cancer Institute, Bethesda, Md, in a population of patients with adenocarcinomas of the pancreas. Patients who were entered on to studies of intraoperative or conventional radiation therapy used as adjuncts to surgical resection.[7,8] The morbidity, mortality, and efficacy of disease control are analyzed.

*RT indicates regional total pancreatectomy; IORT, intraoperative radiation therapy; EBRT, external-beam radiation therapy; RTA, regional total pancreatectomy with arterial resection; and RS, regional subtotal pancreatectomy.

†Staging: I indicates confined to pancreas; II, peripancreatic or vascular invasion; III, nodal involvement; and IV, visceral or peritoneal spread.

‡No disease recurrence at time of death or last follow-up.

§Alive at time of last follow-up.

PATIENTS AND METHODS

Patients

Twenty patients had a regional pancreatectomy performed at the National Cancer Institute. The patients were among groups that were accrued into prospective pilot studies that investigated the role of intraoperative radiotherapy in treating various malignant neoplasms and into prospectively randomized studies that compared adjunctive intraoperative therapy with conventional postoperative radiotherapy in treating patients with resectable pancreatic cancers.[7] Patients with biopsy-proved adenocarcinomas of the pancreas who, on exploration, were found to have localized disease without visceral or peritoneal metastases underwent a pancreatic resection. Most patients received either intraoperative radiation of the resection bed or postoperative external-beam fractionated radiation. Patients with tumor involvement of the portal vein or of the peripancreatic major visceral arterial tree underwent a regional resection. The patients with pancreatic cancer who had a regional pancreatectomy form the basis of this report (Table 1).

The 20 patients who underwent a regional pancreatectomy included 11 men and nine women. The median age was 58 years, with a range of 42 to 74 years. No patient had stage I disease (confined to the pancreas), three patients had stage II disease (local extension into the duodenum or peripancreatic vasculature), and 15 patients had stage III disease (regional lymph node involvement). Two patients had stage IV disease (metastatic spread); both patients with stage IV disease were considered intraoperatively to have localized disease, but on pathologic review of the resected specimen, they were found to have microscopic discontinuous peritoneal implants.

Surgery

Patients who underwent a regional pancreatectomy had operative procedures performed according to the methods described by Fortner.[3,5] Patients had resections that included a total pancreatectomy (19 patients) or a subtotal pancreatectomy that removed the pancreatic head and neck (one patient), extirpation of the extrahepatic bile duct below the bifurcation with incontinuity

cholecystectomy, subtotal distal gastrectomy, total duodenectomy, splenectomy (19 patients), complete regional lymph node dissection (peripancreatic, hepatic, celiac, superior mesenteric, upper para-aortic, and upper paracaval), and removal of the intrapancreatic portion of the portal vein. The portal vein was reconstructed by an end-to-end anastomosis in all patients; this was performed without portal venous shunting or systemic heparinization. Visceral arterial resections and reconstructions were performed in three patients: one patient had an aberrant common hepatic artery arising from the superior mesenteric artery that was resected from its origin to the hepatic bifurcation and that was replaced with an arterial bypass constructed from the splenic artery; and two patients required resection of the origin of the superior mesenteric artery that was reconstructed with an anastomosis of the residual artery to the aorta. Biliary reconstruction was performed by an end-to-side choledochojejunostomy. An end-to-side gastrojejunostomy was performed in all patients. An end-to-side, double-layer pancreaticojejunostomy was constructed in the single patient who had a subtotal pancreatectomy.

Radiotherapy

Radiotherapy was administered to 17 patients. Patients received, after informed consent, either intraoperative radiation at the time of surgery to the resection bed or conventional fractionated external-beam radiation postoperatively to the upper region of the abdomen. Patients with negative regional lymph nodes did not receive radiation therapy. Three patients were part of a pilot study in which all patients received intraoperative radiation, while 17 patients were entered into a protocol that randomly assigned participants to receive either intraoperative radiation or conventional therapy (defined as no radiation for tumors confined to the pancreas and as fractionated postoperative external-beam radiation for tumors with extrapancreatic or nodal spread).

Intraoperative radiation was delivered following resection and vascular reconstruction but before gastrointestinal anastomosis. Patients received 20 Gy of radiation in a single dose using 9 to 11 meV delivered by a linear accelerator.[8] Patients typically received intraoperative radiotherapy to the pancreatic bed, celiac and superior mesenteric axes, porta hepatis, upper abdominal aorta and vena cava, and base of the left diaphragm. Conventional external-beam radiotherapy was delivered using 6- to 10-mV photons in anterior-posterior opposed fields to the upper region of the abdomen. Patients received a total of 45 to 50 Gy in 1.2 to 1.8 Gy/d fractions delivered five days per week during five to seven weeks.

Eleven patients received intraoperative radiotherapy, and six patients received external-beam radiotherapy. Three patients were not irradiated, one patient because of pathologically negative lymph nodes and two patients because of early postoperative deaths.

Analysis

All patients who underwent a regional pancreatectomy were scored for the type and severity of postoperative complications. All deaths that occurred within the initial hospitalization for surgery were considered to be related to treatment. All patients were followed up clinically at monthly intervals until recurrence or death. Pathologic documentation of local or distant recurrent disease was obtained in all patients by autopsy or by surgical exploration performed at the time of suspected recurrence. The time to disease recurrence, the time to local recurrence (defined as a recurrence anywhere within the peritoneum or retroperitoneum exclusive of isolated metastases to the liver), and the overall survival times were determined by life-table analysis.

RESULTS

Overall Results

Twenty patients underwent a regional pancreatectomy, with the patient characteristics, type of resection, type of adjunctive radiotherapy, treatment complications, and outcome detailed in Table 1. The overall results are summarized in Table 2.

Table 2.—Complications and Disease Control in 20 Patients Who Underwent Regional Pancreatectomy

Category	No. (%)

Disease-free interval (median), mo	9.0 (. . .)
Local tumor control	4 (20)

Surgery

One patient received a subtotal resection of the pancreatic head, while 19 patients had a total pancreatectomy. The median operative time was ten hours (range, five to 20 hours). The median operative blood requirement was 10.5 U (range, 3 to 40 U).

Portal vein resection with an end-to-end reanastomosis was performed in all patients. The median length of portal vein that was resected was 4.0 cm (range, 2 to 6 cm), and the median duration of portal vein clamp time was 18 minutes (range, eight to 25 minutes).

Pancreatic visceral arterial resections were performed in three patients. One patient had a resection of an aberrant hepatic artery that was reconstructed by an anastomosis of the celiac stump of the splenic artery to the hepatic arterial remnant. Two patients had sleeve resections of the base of the superior mesenteric artery that were reconstructed by an anastomosis of the superior mesenteric arterial remnant to the aorta. No prosthetic arterial grafts were used in any patient.

Disease Control

Survival of the 20 patients who underwent a regional pancreatectomy was 50% at 12 months, 20% at 24 months, and 10% at 36 months. The median survival was 12.0 months. One patient remains alive at 50 months. Three patients died of postoperative complications, free of cancer. Two patients died of cerebrovascular accidents, free of malignant neoplasms, during follow-up (at 18 and 39 months). Figure 1 illustrates the actuarial survival curve for all patients.

The median time to disease recurrence was 9.0 months. Two patients died without recurrence at 18 and 39 months, and one patient is alive, free of disease at 50 months. Three patients died in the postoperative period without pathologic evidence of residual or recurrent disease, while one patient who died of complications at two months had recurrent disease at the time of death. The actuarial plot of disease recurrence is given in Fig 2.

Local disease failure occurred in 14 patients (70%), defined as failure within the retroperitoneum or on the peritoneal surfaces. Of the 16 patients who survived surgery, three patients (19%) had local disease control at the time of death or at last follow-up. The median time to local disease recurrence was 9.0 months.

Treatment Mortality

Four patients (20%) died of complications of treatment. One patient who manifested no immediate clinical postop-

Fig 1.—Life-table plot of survival of 20 patients who underwent regional pancreatectomy at National Cancer Institute, Bethesda, Md. Patients alive or patients who died free of cancer are censored and are represented as tic marks at time of death or last follow-up.

Fig 2.—Life-table plot of disease-free survival of 20 patients who underwent regional pancreatectomy at National Cancer Institute, Bethesda, Md. Patients free of recurrence are censored and are represented as tic marks at time of death or last follow-up.

erative complications died suddenly of a myocardial infarction one month after treatment. One patient who underwent an extensive extirpation that required resection of a substantial segment of the superior mesenteric artery developed a biliary fistula with intra-abdominal abscesses one week postoperatively. The patient developed episodes of sepsis, small intestinal fistulas, and multiple-organ failure. The patient died two months following surgery. One patient developed mesenteric arterial thrombosis two weeks postoperatively that resulted in infarction of most of the small intestine. The patient developed multiple gastrointestinal fistulas, sepsis, and multiple-organ failure. The patient died two months postoperatively. One patient developed portal venous thrombosis one week postoperatively and went on to develop multiple gastrointestinal fistulas; this patient died of hepatic failure two months postoperatively.

Treatment Complications

Postoperative complications developed in 11 patients (55%), and these are summarized in Tables 1 and 2. Infectious complications were frequent, with five patients (25%) developing bacterial peritonitis, intra-abdominal abscesses, or wound infections. Sepsis with multiple-organ failure occurred in three patients (15%). Enteric or biliary fistulas developed in two patients (10%) and were associated with intra-abdominal sepsis. Mesenteric vascular thrombosis and infarction occurred in two patients (10%), with one patient having thrombosis of the superior mesenteric artery and with the other patient having portal venous occlusion. Persistent chylous ascites developed in two patients (10%); this condition spontaneously resolved by three months postoperatively in one patient and required peritoneovenous shunting in the other patient. One patient had a prolonged postoperative ileus (14 days). One patient suffered a cardiac arrest and could not be resuscitated; autopsy revealed a myocardial infarction with no intra-abdominal pathologic condition.

Late Events

Sixteen patients survived a regional pancreatectomy and were discharged from the hospital. No patients suffered from intractable diabetes or malabsorption that required hospitalization for control. All patients required insulin (4 to 60 U/d, typically in two divided doses). All patients required pancreatic enzyme replacement (4 to 10 capsules with each meal), including the single patient in the series with a subtotal pancreatic resection. All patients suffered some weight loss (5% to 15% of the discharge weight) initially on leaving the hospital; this weight loss typically stabilized or was reversed within three months of hospital discharge.

Late complications developed in some patients (Table 1). Two patients were considered to have alimentation and nutritional problems that were severe enough to require special dietary supplements. One patient developed a gastric bezoar that was composed of vegetable material two years postoperatively and required endoscopic removal. One patient suffered repeated bouts of lower gastrointestinal tract bleeding, beginning two years postoperatively and eluding diagnostic attempts at localization. Arteriography ultimately suggested scattered areas of arteriovenous ectasia in the colon, and the bleeding episodes resolved following a subtotal colectomy. No malignant disease was present at the time of laparotomy.

In some patients, late events developed that were considered to be unrelated to the treatment undertaken for pancreatic cancer. One patient developed a localized primary adenocarcinoma of the breast 18 months after a pancreatectomy and underwent a mastectomy. The patient ultimately died of a myocardial infarction and was found to have metastatic pancreatic cancer in the liver at the time of death. One patient with a history of renal stones developed renal calculi that required lithotripsy and endoscopic removal one year after a pancreatectomy. Two patients died of strokes, free of recurrent pancreatic cancer, at 18 and 39 months following a pancreatectomy.

Adjuvant Radiotherapy

Intraoperative radiotherapy was delivered to 11 patients, and conventional postoperative external-beam radiation was given to six patients. Three patients received no radiation therapy. There were no significant differences in

Table 3.—Comparison of Results of Patients Who Underwent Regional Pancreatectomy for Adenocarcinoma of Pancreas

Series Study, y	No. of Patients	No. (%)					Median Survival, mo
		Mortality	Morbidity	Survival, mo			
				12	24	36	
Fortner[5] 1984	35	9 (26)	41 (67)	14 (40)	3 (9)	1 (3)	12.5

overall survival between the patient group that received intraoperative irradiation (12-month median survival) and the patient group that received either no radiation or conventional radiotherapy (ten-month median survival). Although not reaching statistical significance, there was a trend toward earlier disease recurrence among patients who received no radiation or conventional irradiation (75% recurrence at any site and 75% local recurrence at 12 months), compared with the patients who received intraoperative irradiation (56% recurrence at any site and 44% local recurrence at 12 months).

COMMENT

Adenocarcinoma of the pancreas is an aggressive visceral malignant neoplasm, claiming nearly 25 000 lives yearly in the United States.[1] Pancreatic carcinoma is a highly lethal disease, with only approximately 1% of patients successfully cured by surgical intervention.[1] Surgical removal of the neoplasm is the only treatment modality that potentially can result in cure, but only about 15% of all patients with pancreatic cancers are found at operation to have lesions sufficiently localized to permit resection. The expected five-year survival rates of patients with resected adenocarcinoma of the pancreatic parenchyma is under 10%, and about 50% of patients who undergo resection have local recurrences within the tumor bed.[1,2] A pancreatduodenectomy (Whipple's operation) has been the surgical procedure traditionally utilized for pancreatic resections, although a total pancreatectomy has been advocated by some surgeons.

The regional pancreatectomy was initially described in 1973, by Fortner[3] as a resective procedure potentially applicable to locally advanced pancreatic cancers. The procedure was considered to enhance disease control possibly by extirpating all tissues in the region of the pancreas that could harbor residual neoplastic cells that were spread from the primary tumor. The regional pancreatectomy consists of en bloc resection of the pancreatic head or entire gland, the duodenum, the regional lymph nodes (peripancreatic, celiac, hepatic, superior mesenteric, upper para-aortic, and upper para-caval), much of the extrahepatic bile duct, and the intrapancreatic portion of the portal vein. The procedure involves reconstuction of the sleeve-resected portal vein by an end-to-end anastomosis. The regional pancreatectomy also involves visceral arterial resection in patients with neoplastic involvement of the celiac, hepatic, or superior mesenteric arteries.

The initial report of the regional pancreatectomy described four patients. There was a 25% operative mortality and a six-month survival of 25%.[3] In 1977, Fortner and colleagues[4] reported on a series of 18 patients who had undergone a regional pancreatectomy at Memorial Sloan-Kettering Cancer Center, with a mortality of 17% and a 62% one-year actuarial survival rate. It was suggested that the regional pancreatectomy improved the resectability rate of patients with pancreatic neoplasms, allowed the resection of large lesions that were considered untreatable by the conventional Whipple's operation or by a total pancreatectomy, and resulted in improved survival, compared with patients who undergo conventional pancreatic resections.

By 1984, Fortner[5] accumulated a series of 61 patients with regional pancreatic resections, including 35 patients with adenocarcinoma of the pancreas, 21 patients with periampullary tumors, islet cell tumors, or other malignant pancreatic lesions, and five patients with benign conditions. The overall treatment-related mortality was 23%. The mortality decreased to 8% during the three years that immediately preceded the report. For patients with adenocarcinoma of the pancreas who underwent a regional resection, the median survival was 13 months. The longest surviving patient died with cancer at 53 months following surgery. Patients who underwent a regional pancreatectomy for periampullary malignant neoplasms or islet cell tumors had a median survival of 40 months.

The utility of the regional pancreatectomy has been debated by pancreatic surgeons.[6] Proponents of regional resections have claimed that the procedure allows resection of lesions that were too extensive for conventional Whipple's or total pancreatic resections and that the regional procedure produces long-term survival in some patients. Critics of the regional pancreatectomy point out that, while the operation requires considerable technical skill and hospital resources, it does not substantially enhance survival in most patients with pancreatic cancer. Most centers that perform large numbers of surgical procedures for pancreatic adenocarcinoma consider the regional pancreatectomy to be an experimental procedure. Few institutions have amassed any experience with the regional pancreatectomy. The present series reports the experience with regional resection at the National Cancer Institute and attempts to interpret the utility of the procedure in patients with locally advanced pancreatic adenocarcinoma.

Twenty patients underwent a regional pancreatectomy at the National Cancer Institute. The overall morbidity was 55%, and the treatment mortality was 20%; these rates are consistent with those reported by Fortner[5] for patients who undergo regional resections for adenocarcinoma of the pancreatic parenchyma (Table 3). Although some isolated series have shown highly favorable mortality and complication rates for pancreatic resections, the morbidity and mortality of regional resections correspond closely to the average complication rates of multiple series of conventional pancreatic resections for cancer. Whipple's operations show an average 20% mortality and 52% morbidity in collected series, and total pancreatectomies demonstrate 22% mortality and 53% morbidity.[1] Consequently, it may be suggested that the regional resection can be performed with an overall risk that does not substantially exceed that of Whipple's or total pancreatic resections. The morbidity of the regional pancreatectomy may be reduced as surgical experience increases. In the present series, complications

developed in seven (47%) of 15 patients whose operations were performed by experienced attending surgeons (defined as surgeons who had performed at least five pancreatic resections of any type for malignant disease), but complications occurred in four (80%) of five patients who had resections performed by less-experienced attending surgeons (defined as surgeons who had performed fewer than five pancreatic resections).

The survival rates in the present series were 50% at 12 months and 10% at 36 months, closely approximating the results of Fortner's[5] series (Table 3). In combined series of pancreatic resections for pancreatic adenocarcinomas, the average three-year survival has been reported as 13% for Whipple's operations and as 18% for total pancreatectomies.[1] There is no substantial difference, therefore, in the expected survivals of patients who undergo a regional pancreatectomy as compared with pancreatic resections that do not involve the portal vein or regional nodes. Direct comparisons of survival rates may be misleading, however, since patients who undergo a regional pancreatectomy typically have disease that is considered too advanced to allow a conventional Whipple's resection or a total pancreatectomy. The population of patients with regional resections represents a group with advanced disease and a poor prognosis. In the present series, there were no patients with stage I disease confined within the pancreas who would be considered as candidates for resection by a conventional Whipple's operation or a total pancreatectomy. Consequently, some patients may be salvaged by a regional pancreatectomy who could not be resected by a conventional pancreatectomy.

In the present series, no significant differences developed in morbidity, mortality, or disease control between the patient groups that received intraoperative radiotherapy and those that received conventional external-beam therapy or no radiotherapy. There was, however, a trend toward delayed disease recurrence in the patients who received intraoperative irradiation. Since the overall morbidity and mortality rates in the present series were similar to those reported by Fortner[5] in patients who received a regional resection without radiation, it can be reasonably suggested that adjunctive radiotherapy does not substantially increase the risk of treatment-related morbidity following a regional pancreatectomy.

General conclusions may be drawn from the present experience and from the literature reporting on regional pancreatectomy. Regional resections may be performed on selected patients with locally advanced adenocarcinomas of the pancreas with an expected morbidity of at least 50% and an expected mortality of at least 20%. Complications may be diminished in the hands of surgeons who are experienced in pancreatic resections. The expected median survival of 12 months suggests that a regional pancreatectomy offers no substantial benefit for most patients with pancreatic cancer. However, since approximately 10% of patients may enjoy long-term survival, a regional pancreatectomy should be considered as a treatment option in selected patients at centers with considerable experience in pancreatic surgery. Further investigation appears to be warranted into the possible utility of radiation therapy in conjunction with resection for pancreatic cancer.

Bacteriologic Analysis of Wound Infection Following Major Head and Neck Surgery

Jennifer Rubin, MD; Jonas T. Johnson, MD; Robin L. Wagner; Victor L. Yu, MD

Wound infection was studied prospectively in 23 (6.5%) of 354 patients who participated in a series of antibiotic trials during major contaminated head and neck surgical procedures. Polymicrobial infection was identified in 22 (96%) of 23 cases. The most commonly encountered organisms were aerobic bacteria (91%), anaerobes (74%), and fungi (48%). All fungal infections resolved without systemic antifungal therapy. It was, therefore, concluded that the presence of fungus represented colonization. The primary treatment of an infected wound is surgical drainage accompanied by broad spectrum antibiotic therapy to prevent sepsis. The value of postoperative wound cultures is unclear. The majority of patients who developed wound infection had a variety of organisms that appeared to be unrelated to the prophylactic antibiotic used, as well as to the particular surgery performed (*Arch Otolaryngol Head Neck Surg* 1988;114:969-972).

Débridement of Wounds With Dakin's Solution

To the Editor.—The article in the April 1988 issue of the ARCHIVES by Kozol and colleagues[1] recommended that we abandon the use of Dakin's solution in open, dirty, necrotic wounds. Unfortunately, this article, like many other reports based on laboratory studies in rats and rabbits, ignores the observations and lessons learned in clinical surgery over many years. A wound that is covered with dead, infected tissue must be débrided one way or another. Any technique, whether it is surgical débridement or frequent dressing changes, will damage normal underlying tissue. The purpose of using frequent dressing changes with half-strength Dakin's solution is to débride rapidly the dead, necrotic, infected tissue. Once this is done, healing can take place regardless of where the neutrophils migrate. Once the wound is clean, application of the dressings with Dakin's solution is stopped and the wound either is allowed to epithelialize or is surgically closed. Furthermore, even though Kozol et al recommend the abandonment of Dakin's and saline solutions and the use of normal saline solution, where are the controls to show that normal saline solution is the solution of choice? Where are the controls to show that surgical débridement does not hurt normal tissue? Finally, why do surgical journals continue to publish these silly little studies that have no bearing on clinical surgery?

1. Kozol RA, Gillies C, Elgebaly SA: Effects of sodium hypochlorite (Dakin's solution) on cells of the wound module. *Arch Surg* 1988;123:420-427.

To the Editor.—Kozol et al conclude that the adverse effects of hypochlorites on various cell lines in their wound module argue against the use of Dakin's solution in open wounds. Unfortunately, extrapolations from cell culture or other "wound facsimiles" to the surgical wound are tenuous at best. Both hypochlorite itself, as well as compounds that generate hypochlorous acid (the active species of all hypochlorite microbicidal formulations), have enjoyed long-term clinical popularity principally because of their efficacy and safety.[1-3]

The apparently contradictory results obtained by Kozol et al may, in part, be explained by the wound module, which bears little similarity to a real wound milieu. The cell culture environment lacks the organic substances (principally proteinaceous components of serum, fibrin, and collagen) of the clinical wound. It is well known that hypochlorites are consumed by organic matter.[4,5] The absence of these organic substances in the wound module precludes consumption, as normally occurs in the clinical wound. Consumption and buffering of hypochlorites by organic matter in the clinical wound accounts for the requirement of higher concentrations of hypochlorites to achieve effective antimicrobial activity in clinical wounds. It also explains wound tolerance of these higher levels of hypochlorite concentration.

Kozol et al do not detail the composition of the Dakin's solution used in their study. Specifically, they do not state whether the hypochlorite was buffered and, if so, what the pH was. Dakin himself modified the formulation, first buffering it with boric acid and then with carbonate.[5] Buffering serves two important functions. First, it reduces the alkalinity of hypochlorite. Even very dilute solutions of unbuffered hypochlorite (laundry bleach) in saline solution have a pH in excess of 10. Second, by reducing the pH, the solution's equilibrium is shifted toward generation of hypochlorous acid: $NaOCl + H^+ \rightleftharpoons HOCl + Na^+$. As noted above, hypochlorous acid is the actual microbicidal species in all hypochlorite formulation. Hence, lower pH translates to greater efficacy and this allows lower concentrations to be used.[5-7]

Hypochlorites have an excellent antimicrobial spectrum and act rapidly against gram-positive and gram-negative bacteria, viruses (including human immunodeficiency virus), fungi, and spores. Resistant organisms do not develop. No adverse local effect has been determined in the clinical wound and no systemic toxicity has been found no matter what the duration of use in recommended concentrations. Actual clinical use has proven to us that hypochlorites are effective tools in wound management.

In Reply.—I would like to thank Drs Raffensperger and Cuono and Mr Barese for their interest in our work. They bring up the dilemma of the applicability of animal and in vitro models to clinical surgery. To this issue, Claude Bernard, the father of experimental medicine, said the following:

I not only conclude that experiments made on animals from the physiological, pathological and therapeutic points of view have results that are applicable to theoretical medicine, but I think that without such comparative study of animals, practical medicine can never acquire scientific character.[1]

The fact that a practice or ritual has been used in surgery for decades does not diminish the value of further scientific evaluation of that practice.

Mr Barese and Dr Cuono point out that organic matter in wounds consumes the hypochlorites. Nobel Prize winner Alexander Fleming addressed this very issue about Dakin's solution and commented that "It loses its antiseptic action so quickly. In ten minutes, it can't do much damage and, after that, nature has two hours' rest in which to recuperate without being interrupted."[2]

Peacock noted that "The history of wound surgery is, in large measure, the history of military surgery."[3] Dakin's solution was popularized during World War I as an alternative to surgical débridement because of logistical problems of wound care in the battlefield. Grossly infected, necrotic wounds should be surgically débrided. Clean, open wounds are most safely cared for with normal saline solution, which in general is not toxic to native cells.

Cancer Surveillance After Augmentation Mammoplasty

To the Editor.—The major point of the article by Silverstein et al[1] in the June 1988 issue of the ARCHIVES entitled "Breast Cancer in Women After Augmentation Mammoplasty" seems to be that augmentation mammoplasty with silicone-gel–filled implants make film-screen mammography, our best diagnostic tool, less sensitive. I must politely disagree.

In conjunction with our mammographer, G. William Ecklund, MD, we have shown that state-of-the-art mammographic cancer surveillance is possible in augmented breasts if specialized techniques are utilized.

Selected patients who have undergone augmentation mammoplasty during the past several years have demonstrated to us the advantages of modified patient positioning and compression techniques to optimize breast tissue visualization (Figure). Five views are routinely utilized for each breast: the standard mediolateral oblique and vertical craniocaudal repeated standard views with anterior compression and a 90° mediolateral compression view. Magnified views, focal compressed magnified views, and the use of lead markers have also helped us in identifying suspicious masses and/or calcifications. A videotape is available to demonstrate these techniques.

By modifying the mammographic examination and supplying appropriate counseling and reassurance about the procedure to both patients and physicians, patient cooperation and improved image quality have been obtained. It is incumbent on the referring physician to convey to the mammographer as much information about the patient as possible, including the type and location of the clinical concerns prompting this study.

Standard (top) and modified (bottom) compressions of mediolateral oblique view of same patient, who had significant capsular contracture in addition to augmentation.

Books

Surgery of the Liver and Biliary Tract, edited by L. H. Blumgart, 1552 pp, $350, New York, Churchill Livingstone Inc, 1988.

Surgery of the Liver and Biliary Tract is destined to become the classic reference for surgeons and students of surgical disease of the right upper quadrant. Professor Blumgart has assembled a host of Western authorities on a wide range of subjects germane to the surgical treatment of diseases of the liver, gallbladder, and bile ducts. The range of this work far surpasses other contemporary works on this subject as witnessed by the sheer mass of this two-volume endeavor.

Divided into 18 major sections, this book encompasses the entire gamut of surgical liver disease beginning with anatomy and pathophysiology and including diagnostic techniques, both radiology and endoscopy, as well as a section on preoperative and postoperative anesthetic and metabolic considerations for the patient with a diseased liver. More mundane problems are also addressed, with more than 150 pages devoted to stone disease of the gallbladder and biliary ducts. Extensive sections on bile duct tumors, bile duct and liver cysts, and liver tumors are complemented by rigorous treatment of hepatic resection techniques as well as radiological and endoscopic palliative procedures. Cirrhosis and portal hypertension, both in the adult and child, and hepatic transplantation round out the final volume.

Unlike many multiauthored texts,

this work exhibits a surprising homogeneity between chapters that reflects both careful editorial supervision and the quality of the individual contributors. Multiple black-and-white photographs and clearly constructed line drawings by a single artist contribute to easy readability.

Priced at $350, this work is not a casual purchase. Nevertheless, it represents very good value considering its scope and breadth. *Surgery of the Liver and Biliary Tract* will certainly take its place as one of the premiere reference works for surgeons who deal with both straightforward and complex disorders of the liver and biliary system. This work is a must for all reference libraries and will be a handsome and often-used addition to the collection of both the experienced hepatobiliary surgeon as well as those entering the field.

GREG VAN STIEGMANN, MD
Denver

Cancer of the Breast, ed 3, edited by William L. Donegan and John S. Spratt, 752 pp, with illus, $99, Philadelphia, WB Saunders Co, 1988.

A spate of new textbooks on breast disease have been published during the past few years. The field may now be overpopulated. A good update of an earlier book, however, is always welcome.

In the third edition of *Cancer of the Breast*, editors William Donegan and John Spratt have assembled 29 other authors, half of them from Louisville, who write of relevant, timely changes in the approach to breast cancer. New material is frequent. The full spectrum of clinical care and much of the related basic science are covered. Controversy has not been covered up. One of the editors, for instance, challenges the widely held belief that screening mammography will reduce the risk of dying of breast cancer.

One of the best chapters in the book is not about new developments. It is a history of breast cancer written by Dr Donegan. The alternating views of breast cancer as primarily systemic vs local are traced over centuries. The classic radical mastectomy, one learns, was described more than 100 years before Halsted. The rise and fall of theories and procedures over the course of 5000 years makes good reading.

The strength of this text is its emphasis on aspects of breast cancer that concern the surgeon. This is not surprising, because both editors are surgical oncologists. The chapter on diagnosis reviews extensively the classic signs of breast cancer and devotes considerable space to biopsy techniques. The section on needle localization biopsy is complete in terms of technique, although one can disagree with the author that an immediate specimen roentgenogram is useful for occult masses as well as for microcalcifications.

The chapters on staging and primary treatment and on surgical management, each among the longest in the book, actually constitute a single description of primary therapy for breast cancer. Illustrations of particular operations are clear, and the accompanying legends are detailed. The book may be worth its $99 price as a surgical atlas of breast procedures alone. Although surgeons may quibble over fine points, the techniques shown are current and acceptable. Best of all, operative techniques are kept in proper perspective with the greater demands of the disease.

The last chapter, on statistical methods in cancer research, is an unexpected bonus. In a day when treatment is dictated primarily by results of randomized studies, it is useful to know the means by which studies should be judged. One section of the chapter is entitled "Principles to Remember." It lists 13 guidelines to be used in designing protocols or interpreting data. For the occasional statistician, the criteria are eye-opening. Another surprise is a review of common statistical methods for determining significance. The commonly used Student's *t* test never seemed so understandable.

Cancer of the Breast does not have as many distinguished contributors as some other recently published texts, but it is unusually clear and to the point. In the final analysis, it may prove to be more useful.

Limited Enrollment: SURGERY BOARDS REVIEW REGISTRATION

Name _____

Address _____

City/State/Zip _____

Phone _____

For: ☐ January 23-29, 1989 – Houston
☐ March 6-12, 1989 – Portland
☐ April 24-30, 1989 – Chicago
☐ October 4-10, 1989 – Chicago

☐ Check is enclosed for $ _____

☐ Please send more information.

Mail today to:

1094 Dawn Lane, Dept. S12
P.O. Box 2218
Terre Haute, IN 47802

*"Accommodations were comfortable..."**

GOALS AND LOCATION: The course is to help you pass your written and oral, or recertification exams. Home study questions are sent upon registration. Your best buy is to repeat the course just before written and oral board exams. The Houston course will be held at the Doubletree at Houston Intercontinental Airport, 15747 John F. Kennedy Blvd., Houston, Texas 77032. The Doubletree has an outdoor pool, whirlpool spa, fine dining and free parking and airport transportation. Rates are $69 single and $88 double. Please wait for instructions before buying travel tickets.

*"...and those little extras...."**

LOWEST AIR FARES: Reliable Travel offers you the lowest air fare – often below super-saver rates. Please call toll-free 1-800-645-6504 ext. 10 and identify yourself with this Osler course for special group fares.

*"...remarkably complete and pleasant."**

PLACEMENT SERVICE: For a practice opportunity write or call (800) 356-7537.

*"...the most education for the money."**

FEES AND C.M.E. CREDITS:
- **C.M.E. Credits Hours: 65 hrs.**
- Practicing Surgeon: $690
- Resident or Fellow: one third off
- Repeating course within 3 years: half price
- **Add 10% for Houston after Jan. 15, 1989.**
- Attendees not in course hotel add $8/day.
- Fees include no lodging or meals.
- $50.00 will reserve your position.
- Most home study materials will be mailed after half of registration fee is received.

*"...home study material was extremely helpful."**

CANCELLATIONS: Refunds subject to $50 fee, will be made until the seminar begins.
- Cancellation after mailing home study material requires retention of half of the fee.

*"I feel [the course] helped me pass the boards."**

In intra-abdominal and gynecologic infection due to indicated organisms

CEFOTAN® IM/IV
(cefotetan disodium)

Does so much for so much less than cefoxitin

For Intravenous or Intramuscular Use
BRIEF SUMMARY

INDICATIONS AND USAGE
TREATMENT: CEFOTAN® (cefotetan disodium) is indicated for the therapeutic treatment of the following infections when caused by susceptible strains of the designated organisms:
Urinary tract infections caused by *E coli, Klebsiella* species (including *K pneumoniae*), *Proteus mirabilis* and *Proteus* sp (which may include the organisms now called *Proteus vulgaris, Providencia rettgeri*, and *Morganella morganii*).
Lower respiratory tract infections caused by *Streptococcus pneumoniae* (formerly *D pneumoniae*), *Staphylococcus aureus* (penicillinase- and nonpenicillinase-producing strains), *Haemophilus influenzae* (including ampicillin-resistant strains), *Klebsiella* species (including *K pneumoniae*), and *E coli*.
Skin and skin structure infections caused by *Staphylococcus aureus* (penicillinase- and nonpenicillinase-producing strains), *Staphylococcus epidermidis,* Streptococcus pyogenes* and *Streptococcus* species (excluding enterococci), and *E coli*.
Gynecologic infections caused by *Staphylococcus aureus*† (including penicillinase- and nonpenicillinase-producing strains), *Staphylococcus epidermidis,* Streptococcus* species (excluding enterococci), *E coli, Proteus mirabilis, Neisseria gonorrhoeae, Bacteroides* species (excluding *B distasonis, B ovatus, B thetaiotaomicron*), *Fusobacterium* species,† and gram-positive anaerobic cocci (including *Peptococcus* and *Peptostreptococcus* species†).
Intra-abdominal infections caused by *E coli, Klebsiella* species (including *K pneumoniae*†), *Streptococcus* species (excluding enterococci), and *Bacteroides* species (excluding *B distasonis, B ovatus, B thetaiotaomicron*).
Bone and joint infections caused by *Staphylococcus aureus*.†
***NOTE:** Some strains of *Staphylococcus epidermidis* are resistant to cefotetan.
† Efficacy for this organism in this organ system was studied in fewer than ten infections.
PROPHYLAXIS: The preoperative administration of CEFOTAN may reduce the incidence of certain postoperative infections in patients undergoing surgical procedures that are classified as clean contaminated or potentially contaminated (eg, cesarean section, abdominal or vaginal hysterectomy, transurethral surgery, biliary tract surgery, and gastrointestinal surgery).
The prophylactic dose of CEFOTAN should be administered 30 to 60 minutes prior to surgery. In patients undergoing cesarean section, CEFOTAN should be administered intravenously after the clamping of the umbilical cord.
If there are signs and symptoms of infection, specimens for culture should be obtained for identification of the causative organism so that appropriate therapeutic measures may be initiated.

CONTRAINDICATIONS
CEFOTAN is contraindicated in patients with known allergy to the cephalosporin group of antibiotics.

WARNINGS
Before therapy with CEFOTAN is instituted, careful inquiry should be made to determine whether the patient has had previous hypersensitivity reactions to cefotetan disodium, cephalosporins, penicillins, or other drugs. This product should be given cautiously to penicillin-sensitive patients. Antibiotics should be administered with caution to any patient who has demonstrated some form of allergy, particularly to drugs. If an allergic reaction to CEFOTAN occurs, discontinue the drug. Serious acute hypersensitivity reactions may require epinephrine and other emergency measures.
Pseudomembranous colitis has been reported with the use of cephalosporins (and other broad-spectrum antibiotics); therefore, it is important to consider its diagnosis in patients who develop diarrhea in association with antibiotic use.
Treatment with broad-spectrum antibiotics may alter normal flora of the colon and may permit overgrowth of clostridia. Studies indicate a toxin produced by *Clostridium difficile* is one primary cause of antibiotic-associated colitis. Cholestyramine and colestipol resins have been shown to bind the toxin in vitro.
Mild cases of colitis may respond to drug discontinuance alone. Moderate to severe cases should be managed with fluid, electrolyte, and protein supplementation as indicated. When the colitis is not relieved by drug discontinuance, or when it is severe, oral vancomycin is the treatment of choice for antibiotic-associated pseudomembranous colitis produced by *C difficile*. Other causes should also be considered.

PRECAUTIONS
GENERAL: As with other broad-spectrum antibiotics, prolonged use of CEFOTAN may result in overgrowth of nonsusceptible organisms. Careful observation of the patient is essential. If superinfection does occur during therapy, appropriate measures should be taken.
In common with many other broad-spectrum antibiotics, CEFOTAN may be associated with a fall in prothrombin activity. Those at risk include patients with renal or hepatic impairment, or poor nutritional state. Prothrombin times should be monitored in patients at risk and exogenous Vitamin K administered as indicated.
CEFOTAN should be used with caution in individuals with a history of gastrointestinal disease, particularly colitis.
INFORMATION FOR PATIENTS: As with some other cephalosporins, a disulfiram-like reaction characterized by flushing, sweating, headache, and tachycardia may occur when alcohol (beer, wine, etc) is ingested within 72 hours after CEFOTAN administration. Patients should be cautioned about the ingestion of alcoholic beverages following the administration of CEFOTAN.
DRUG INTERACTIONS: If CEFOTAN and an aminoglycoside are used concomitantly, renal function should be carefully monitored, especially if higher dosages of the aminoglycoside are to be administered or if therapy is prolonged, because of the potential nephrotoxicity and ototoxicity of aminoglycoside antibiotics. Although, to date, nephrotoxicity has not been noted when CEFOTAN was given alone, it is possible that nephrotoxicity may be potentiated if CEFOTAN is used concomitantly with an aminoglycoside.
DRUG/LABORATORY TEST INTERACTIONS: A false positive reaction for glucose in urine may occur with Benedict's or Fehling's solution.
As with other cephalosporins, high concentrations of cefotetan may interfere with measurement of serum and urine creatinine levels of Jaffe reaction and produce false increases in the levels of creatinine reported.
CARCINOGENESIS, MUTAGENESIS, IMPAIRMENT OF FERTILITY: Although long-term studies in animals have not been performed to evaluate carcinogenic potential, no mutagenic potential of cefotetan was found in standard laboratory tests.
Cefotetan has adverse effects on the testes of prepubertal rats. Subcutaneous administration of 500 mg/kg/day (approx 8-16 times the usual adult human dose) on days 6-35 of life (thought to be developmentally analogous to late childhood and prepuberty in humans) resulted in reduced testicular weight and seminiferous tubule degeneration in 10 of 10 animals. Affected cells included spermatogonia and spermatocytes; Sertoli and Leydig cells were unaffected. Incidence and severity of lesions were dose-dependent; at 120 mg/kg/day (approx 2-4 times the usual human dose), only 1 of 10 treated animals was affected, and the degree of degeneration was mild. Similar lesions have been observed in experiments of comparable design with other methylthiotetrazole-containing antibiotics and impaired fertility has been reported, particularly at high dose levels. No testicular effects were observed in 7-week-old rats treated with up to 1000 mg/kg/day SC for 5 weeks, or in infant dogs (3 weeks old) that received up to 300 mg/kg/day IV for 5 weeks. The relevance of these findings to humans is unknown.
USAGE IN PREGNANCY: Pregnancy Category B: Reproduction studies have been performed in rats and monkeys at doses up to 20 times the human dose and have revealed no evidence of impaired fertility or harm to the fetus due to cefotetan. There are, however, no adequate and well-controlled studies in pregnant women. Because animal reproductive studies are not always predictive of human response, this drug should be used during pregnancy only if clearly needed.
USAGE IN NURSING MOTHERS: Cefotetan is excreted in human milk in very low concentrations. Caution should be exercised when cefotetan is administered to a nursing woman.
PEDIATRIC USE: Safety and effectiveness in children have not been established.

ADVERSE REACTIONS
In clinical studies the following adverse effects were considered related to CEFOTAN therapy.
Gastrointestinal symptoms occurred in 1.5 percent of patients; the most frequent were diarrhea (1 in 80) and nausea (1 in 700).
Hematologic laboratory abnormalities occurred in 1.4 percent of patients and included eosinophilia (1 in 200), positive direct Coombs' test (1 in 250), and thrombocytosis (1 in 300).
Hepatic enzyme elevations occurred in 1.2 percent of patients and included a rise in SGPT (1 in 150), SGOT (1 in 300), alkaline phosphatase (1 in 700), and LDH (1 in 700).
Hypersensitivity reactions were reported in 1.2 percent of patients and included rash (1 in 150) and itching (1 in 700).
Local effects were reported in less than one percent of patients and included phlebitis at the site of injection (1 in 300), and discomfort (1 in 500).

DOSAGE AND ADMINISTRATION
TREATMENT: The usual adult dosage is 1 or 2 grams of CEFOTAN administered intravenously or intramuscularly every 12 hours for 5 to 10 days. Proper dosage and route of administration should be determined by the condition of the patient, severity of the infection, and susceptibility of the causative organism.

GENERAL GUIDELINES FOR DOSAGE OF CEFOTAN

Type of Infection	Daily Dose	Frequency and Route
Urinary Tract	1-4 grams	500 mg every 12 hours IV or IM 1 or 2 g every 24 hours IV or IM 1 or 2 g every 12 hours IV or IM
Other Sites	2-4 grams	1 or 2 g every 12 hours IV or IM
Severe	4 grams	2 g every 12 hours IV
Life-Threatening	6* grams	3 g every 12 hours IV

*Maximum daily dosage should not exceed 6 grams.

PROPHYLAXIS: To prevent postoperative infection in clean contaminated or potentially contaminated surgery in adults, the recommended dosage is 1 or 2 g of CEFOTAN administered once, intravenously, 30 to 60 minutes prior to surgery. In patients undergoing cesarean section, the dose should be administered as soon as the umbilical cord is clamped.
IMPAIRED RENAL FUNCTION: When renal function is impaired, a reduced dosage schedule must be employed. The following dosage guidelines may be used.

DOSAGE GUIDELINES FOR PATIENTS WITH IMPAIRED RENAL FUNCTION

Creatinine Clearance mL/min	Dose	Frequency
>30	Usual Recommended Dose*	Every 12 hours
10-30	Usual Recommended Dose*	Every 24 hours
<10	Usual Recommended Dose*	Every 48 hours

*Dose determined by the type and severity of infection, and susceptibility of the causative organism.

Cefotetan is dialyzable and it is recommended that for patients undergoing intermittent hemodialysis, one-quarter of the usual recommended dose be given every 24 hours on days between dialysis and one-half the usual recommended dose on the day of dialysis.

HOW SUPPLIED
CEFOTAN is a dry, white to pale yellow powder supplied in vials containing cefotetan disodium equivalent to 1 g and 2 g cefotetan activity for intravenous and intramuscular administration. The 1 g dose is available in 10 mL and 100 mL vials, and the 2 g dose is available in 20 mL and 100 mL vials. The vials should not be stored at temperatures above 22°C and should be protected from light.
1 g in 10 mL vial (NDC 0038-0376-10); 2 g in 20 mL vial (NDC 0038-0377-20); 1 g in 100 mL vial (NDC 0038-0376-11); 2 g in 100 mL vial (NDC 0038-0377-21)

Ace 27.3.89

Rocephin® IV·IM

ceftriaxone sodium/Roche

Before prescribing, please consult complete product information, a summary of which follows:

INDICATIONS AND USAGE: Rocephin is indicated for the treatment of the following infections when caused by susceptible organisms:

LOWER RESPIRATORY TRACT INFECTIONS caused by *Strep. pneumoniae, Streptococcus* species (excluding enterococci), *Staph. aureus, H. influenzae, H. parainfluenzae, Klebsiella* species (including *K. pneumoniae*), *E. coli, E. aerogenes, Proteus mirabilis* and *Serratia marcescens.*

SKIN AND SKIN STRUCTURE INFECTIONS caused by *Staph. aureus, Staph. epidermidis, Streptococcus* species (excluding enterococci), *E. cloacae, Klebsiella* species (including *K. pneumoniae*), *Proteus mirabilis* and *Pseudomonas aeruginosa.*

URINARY TRACT INFECTIONS (complicated and uncomplicated) caused by *E. coli, Proteus mirabilis, Proteus vulgaris, M. morganii* and *Klebsiella* species (including *K. pneumoniae*).

UNCOMPLICATED GONORRHEA (cervical/urethral and rectal) caused by *Neisseria gonorrhoeae*, including both penicillinase and nonpenicillinase producing strains.

PELVIC INFLAMMATORY DISEASE caused by *N. gonorrhoeae.*

BACTERIAL SEPTICEMIA caused by *Staph. aureus, Strep. pneumoniae, E. coli, H. influenzae* and *K. pneumoniae.*

BONE AND JOINT INFECTIONS caused by *Staph. aureus, Strep. pneumoniae, Streptococcus* species (excluding enterococci), *E. coli, P. mirabilis, K. pneumoniae* and *Enterobacter* species.

INTRA-ABDOMINAL INFECTIONS caused by *E. coli* and *K. pneumoniae.*

MENINGITIS caused by *H. influenzae, N. meningitidis* and *Strep. pneumoniae.* Ceftriaxone has also been used successfully in a limited number of cases of meningitis and shunt infections caused by *Staph. epidermidis* and *E. coli.*

SURGICAL PROPHYLAXIS: Preoperative administration of a single 1 gm dose may reduce incidence of postoperative infections in patients undergoing surgical procedures classified as contaminated or potentially contaminated (*e.g.*, vaginal or abdominal hysterectomy) and in those for whom infection at the operative site presents serious risk (*e.g.*, during coronary artery bypass surgery).

Although ceftriaxone has been shown to have been as effective as cefazolin in the prevention of infection following coronary artery bypass surgery, no placebo-controlled trials have been conducted to evaluate any cephalosporin antibiotic in the prevention of infection following coronary artery bypass surgery. When administered before indicated surgical procedures, a single 1 gm dose provides protection from most infections due to susceptible organisms for duration of procedure.

SUSCEPTIBILITY TESTING: Before instituting treatment with Rocephin, appropriate specimens should be obtained for isolation of the causative organism and for determination of its susceptibility to the drug. Therapy may be instituted prior to obtaining results of susceptibility testing.

CONTRAINDICATIONS: Rocephin is contraindicated in patients with known allergy to the cephalosporin class of antibiotics.

WARNINGS: BEFORE THERAPY WITH ROCEPHIN IS INSTITUTED, CAREFUL INQUIRY SHOULD BE MADE TO DETERMINE WHETHER THE PATIENT HAS HAD PREVIOUS HYPERSENSITIVITY REACTIONS TO CEPHALOSPORINS, PENICILLINS OR OTHER DRUGS. THIS PRODUCT SHOULD BE GIVEN CAUTIOUSLY TO PENICILLIN-SENSITIVE PATIENTS. ANTIBIOTICS SHOULD BE ADMINISTERED WITH CAUTION TO ANY PATIENT WHO HAS DEMONSTRATED SOME FORM OF ALLERGY, PARTICULARLY TO DRUGS. SERIOUS ACUTE HYPERSENSITIVITY REACTIONS MAY REQUIRE THE USE OF SUBCUTANEOUS EPINEPHRINE AND OTHER EMERGENCY MEASURES.

Pseudomembranous colitis has been reported with the use of cephalosporins (and other broad-spectrum antibiotics); therefore, it is important to consider its diagnosis in patients who develop diarrhea in association with antibiotic use.

Treatment with broad-spectrum antibiotics alters the normal flora of the colon and may permit overgrowth of clostridia. Studies indicate a toxin produced by *Clostridium difficile* is one primary cause of antibiotic-associated colitis. Cholestyramine and colestipol resins have been shown to bind to the toxin *in vitro*.

Mild cases of colitis respond to drug discontinuance alone. Moderate to severe cases should be managed with fluid, electrolyte and protein supplementation as indicated.

When the colitis is not relieved by drug discontinuance or when it is severe, oral vancomycin is the treatment of choice for antibiotic-associated pseudomembranous colitis produced by *C. difficile*. Other causes of colitis should also be considered.

Rarely, shadows suggesting sludge have been detected by sonograms of the gallbladder in asymptomatic and symptomatic patients. This appears to be reversible on discontinuation of therapy. In a few symptomatic patients receiving higher than usual doses, who underwent surgery, sludge containing traces of ceftriaxone was recovered from surgical specimens. Discontinue therapy in patients who develop signs or symptoms suggestive of gallbladder disease; consider conservative management.

PRECAUTIONS: *GENERAL:* Although transient elevations of BUN and serum creatinine have been observed, at the recommended dosages, the nephrotoxic potential of Rocephin is similar to that of other cephalosporins.

Ceftriaxone is excreted via both biliary and renal excretion (see Clinical Pharmacology). Therefore, patients with renal failure normally require no adjustment in dosage when usual doses of Rocephin are administered, but concentrations of drug in the serum should be monitored periodically. If evidence of accumulation exists, dosage should be decreased accordingly.

Dosage adjustments should not be necessary in patients with hepatic dysfunction; however, in patients with both hepatic dysfunction and significant renal disease, Rocephin dosage should not exceed 2 gm daily without close monitoring of serum concentrations.

Alterations in prothrombin times have occurred rarely in patients treated with Rocephin. Patients with impaired vitamin K synthesis or low vitamin K stores (*e.g.*, chronic hepatic disease and malnutrition) may require monitoring of prothrombin time during Rocephin treatment. Vitamin K administration (10 mg weekly) may be necessary if the prothrombin time is prolonged before or during therapy.

Prolonged use of Rocephin may result in overgrowth of nonsusceptible organisms. Careful observation of the patient is essential. If superinfection occurs during therapy, appropriate measures should be taken.

Rocephin should be prescribed with caution in individuals with a history of gastrointestinal disease, especially colitis.

CARCINOGENESIS, MUTAGENESIS, IMPAIRMENT OF FERTILITY: Carcinogenesis: Considering the maximum duration of treatment and the class of the compound, carcinogenicity studies with ceftriaxone in animals have not been performed. The maximum

ROCEPHIN® (ceftriaxone sodium/Roche)

duration of animal toxicity studies was six months.

Mutagenesis: Genetic toxicology tests included the Ames test, a micronucleus test and a test for chromosomal aberrations in human lymphocytes cultured *in vitro* with ceftriaxone. Ceftriaxone showed no potential for mutagenic activity in these studies.

Impairment of Fertility: Ceftriaxone produced no impairment of fertility when given intravenously to rats at daily doses up to 586 mg/kg/day, approximately 20 times the recommended clinical dose of 2 gm/day.

PREGNANCY: Teratogenic Effects: Pregnancy Category B. Reproductive studies have been performed in mice and rats at doses up to 20 times the usual human dose and have no evidence of embryotoxicity, fetotoxicity or teratogenicity. In primates, no embryotoxicity or teratogenicity was demonstrated at a dose approximately three times the human dose.

There are, however, no adequate and well-controlled studies in pregnant women. Because animal reproductive studies are not always predictive of human response, this drug should be used during pregnancy only if clearly needed.

Nonteratogenic Effects: In rats, in the Segment I (fertility and general reproduction) and Segment III (perinatal and postnatal) studies with intravenously administered ceftriaxone, no adverse effects were noted on various reproductive parameters during gestation and lactation, including postnatal growth, functional behavior and reproductive ability of the offspring, at doses of 586 mg/kg/day or less.

NURSING MOTHERS: Low concentrations of ceftriaxone are excreted in human milk. Caution should be exercised when Rocephin is administered to a nursing woman.

PEDIATRIC USE: Safety and effectiveness of Rocephin in neonates, infants and children have been established for the dosages described in the Dosage and Administration section. *In vitro* studies have shown ceftriaxone, like some other cephalosporins, can displace bilirubin from serum albumin. Exercise caution before administration to hyperbilirubinemic neonates, especially prematures.

ADVERSE REACTIONS: Rocephin is generally well tolerated. In clinical trials, the following adverse reactions, which were considered to be related to Rocephin therapy or of uncertain etiology, were observed:

LOCAL REACTIONS—pain, induration or tenderness at the site of injection (1%). Less frequently reported (less than 1%) was phlebitis after I.V. administration.

HYPERSENSITIVITY—rash (1.7%). Less frequently reported (less than 1%) were pruritus, fever or chills.

HEMATOLOGIC—eosinophilia (6%), thrombocytosis (5.1%) and leukopenia (2.1%). Less frequently reported (less than 1%) were anemia, neutropenia, lymphopenia, thrombocytopenia and prolongation of the prothrombin time.

GASTROINTESTINAL—diarrhea (2.7%). Less frequently reported (less than 1%) were nausea or vomiting, and dysgeusia.

HEPATIC—elevations of SGOT (3.1%) or SGPT (3.3%). Less frequently reported (less than 1%) were elevations of alkaline phosphatase and bilirubin.

RENAL—elevations of the BUN (1.2%). Less frequently reported (less than 1%) were elevations of creatinine and the presence of casts in the urine.

CENTRAL NERVOUS SYSTEM—headache or dizziness were reported occasionally (less than 1%).

GENITOURINARY—moniliasis or vaginitis were reported occasionally (less than 1%).

MISCELLANEOUS—diaphoresis and flushing were reported occasionally (less than 1%).

Other rarely observed adverse reactions (less than 0.1%) include leukocytosis, lymphocytosis, monocytosis, basophilia, a decrease in the prothrombin time, jaundice, gallbladder sludge, glycosuria, hematuria, anaphylaxis, bronchospasm, serum sickness, abdominal pain, colitis, flatulence, dyspepsia, palpitations and epistaxis.

DOSAGE AND ADMINISTRATION: Rocephin may be administered intravenously or intramuscularly. The usual adult daily dose is 1 to 2 gm given once a day (or in equally divided doses twice a day) depending on the type and severity of the infection. The total daily dose should not exceed 4 grams.

For the treatment of serious miscellaneous infections in children, other than meningitis, the recommended total daily dose is 50 to 75 mg/kg (not to exceed 2 grams), given in divided doses every 12 hours.

Generally, Rocephin therapy should be continued for at least two days after the signs and symptoms of infection have disappeared. The usual duration is 4 to 14 days; in complicated infections longer therapy may be required.

In the treatment of meningitis, a daily dose of 100 mg/kg (not to exceed 4 grams), given in divided doses every 12 hours, should be administered with or without a loading dose of 75 mg/kg.

For the treatment of uncomplicated gonococcal infections, a single intramuscular dose of 250 mg is recommended.

For preoperative use (surgical prophylaxis), a single dose of 1 gm administered 1/2 to 2 hours before surgery is recommended.

When treating infections caused by *Streptococcus pyogenes*, therapy should be continued for at least ten days.

No dosage adjustment is necessary for patients with impairment of renal or hepatic function; however, blood levels should be monitored in patients with severe renal impairment (*e.g.*, dialysis patients) and in patients with both renal and hepatic dysfunctions.

HOW SUPPLIED: Rocephin (ceftriaxone sodium/Roche) is supplied as a sterile crystalline powder in glass vials and piggyback bottles. The following packages are available:

Vials containing 250 mg, 500 mg, 1 gm or 2 gm equivalent of ceftriaxone; piggyback bottles containing 1 gm or 2 gm equivalent of ceftriaxone; bulk pharmacy containers containing 10 gm equivalent of ceftriaxone (NOT FOR DIRECT ADMINISTRATION).

Also supplied as a sterile crystalline powder as follows:

ADD-Vantage Vials** containing 1 gm or 2 gm equivalent of ceftriaxone.

Also supplied premixed as a frozen iso-osmotic, sterile, nonpyrogenic solution of ceftriaxone sodium in 50 mL single dose plastic containers,† as follows:

1 gm equivalent of ceftriaxone, iso-osmotic with approximately 1.9 gm dextrose hydrous, USP added.

2 gm equivalent of ceftriaxone, iso-osmotic with approximately 1.2 gm dextrose hydrous, USP added.

NOTE: Rocephin in the frozen state should not be stored above -20°C.

PARTNERS PRACTICING GOOD MEDICINE.

Bring your outstanding surgical skills to the Southern California Permanente Medical Group and experience the freedom to focus on patient work. Not paperwork.

We are an HMO multispecialty group practice — a partnership composed of and managed by SCPMG physicians.

Opportunities exist for board eligible/certified **Surgeons** with a combined practice of Peripheral Vascular and General Surgery.

Consider the advantages: the finest equipment and latest technology; the availability of consultations with other physicians of distinction; and a broad network of exceptional support personnel backed by the resources of one of the nation's leading HMO's.

Our compensation is competitive and benefits are outstanding. They include: professional liability, medical and dental coverage, vacation and sick leave, continuing education, life insurance and retirement plans. **After two years full-time employment, physicians are eligible to be considered for partnership.**

For a physician application, please call (818) 405-3224 or send your curriculum vitae to: Physician Recruitment, Dept. 78E8, Walnut Center, Pasadena, CA 91188-8854.

PAPERS READ BEFORE THE ANNUAL MEETING OF THE SOCIETY OF SURGICAL ONCOLOGY, NEW ORLEANS, LA, MAY 22 TO MAY 25, 1988—Part II

Conservative Surgery and Radiation Therapy for Early Breast Cancer: Long-term Cosmetic Results 153
Mary Ann Rose, MD, Boston, Mass; Ivo Olivotto, MD, Vancouver, Canada; Blake Cady, MD; Clinton Koufman, MD; Robert Osteen, MD; Barbara Silver; Abram Recht, MD; Jay R. Harris, MD, Boston, Mass
- Satisfactory cosmetic results after conservative operations and radiation therapy are maintained for at least seven years.

Local Recurrent Mammary Carcinoma Failing Multimodality Therapy: A Solution 158
Patricia M. McCormack, MD; Manjit S. Bains, MD; Michael E. Burt, MD, PhD; Nael Martini, MD; Ted Chaglassian, MD; David A. Hidalgo, MD, New York, NY
- Chest wall resection and reconstruction offer significant palliation.

Extent of Lymph Node Dissection in Melanoma of the Trunk or Lower Extremity 162
Daniel G. Coit, MD, Murray F. Brennan, MD, New York, NY
- More extensive lymphadenectomy was not associated with improved survival or decreased recurrence.

Hepatectomy Prolongs Survival of Mice With Induced Liver Metastases 167
Manuel H. Castillo, MD; Ralph J. Doerr, MD; Norman Paolini, Jr, MS; Stephen Cohen, PhD; Martin Goldrosen, PhD, Buffalo, NY
- Hepatectomy prolonged survival when performed after tumor cell injection.

Partial Hepatectomy Augments the Liver's Antitumor Response 170
Ralph Doerr, MD; Manuel Castillo, MD; Paul Evans, MS; Norman Paolini, MS; Martin Goldrosen, PhD; Stephan A. Cohen, PhD, Buffalo, NY
- Partial hepatectomy enhanced the antitumor activity of nonparenchymal liver cells.

Prolongation of Survival of Nude Mice Bearing Human Colon Cancer: Treatment With Yttrium 90–Labeled Anti–Carcinoembryonic Antigen Antibody 175
David M. Hyams, MD; Jose M. Esteban, MD; Barbara G. Beatty, PhD, Duarte, Calif; Philip M. Wanek, RPh, San Diego, Calif; J. David Beatty, MD, Duarte, Calif
- Different dosing regimens had very different results in this animal model.

Survival of Patients With Stage B2 Colon Carcinoma: The Gastrointestinal Tumor Study Group Experience 180
Russell Nauta, MD, Washington, DC; Donald M. Stablein, PhD, Potomac, Md; E. Douglas Holyoke, MD, Buffalo, NY
- Because of excellent survival, patients with stage B2 colon carcinoma are seldom candidates for adjuvant trials of toxic therapy.

Interactions of Human Colorectal Carcinoma Cells With Basement Membranes: Analysis and Correlation With Differentiation 183
George W. Daneker, Jr, MD; Andrew J. Piazza; Glenn D. Steele, Jr, MD, PhD; Arthur M. Mercurio, PhD, Boston, Mass
- Tumor cell adherence and poor differentiation correlate with invasion of basement membranes.

The **ARCHIVES OF SURGERY** (ISSN 0004-0010) is published monthly by the American Medical Association, 535 N Dearborn St, Chicago, IL 60610, and is an official publication of the Association. Second-class postage paid at Chicago, IL 60610 and at additional mailing office.

SUBSCRIPTION RATES—The subscription rates for the ARCHIVES OF SURGERY are as follows: $50 for one year, $85 for two years in the United States and US possessions; all other countries, one year, $60; two years, $105 for surface delivery. (For expedited air delivery to most countries, add $15 surcharge for one-year subscription, $30 for two years.) Rates for subscriptions for delivery to Japan or South Korea are available through exclusive agents—contact the publisher. ***Special rates for residents and medical students in the United States and US possessions are available.*** Address inquiries to the American Medical Association, Circulation and Fulfillment Division, 535 N Dearborn St, Chicago, IL 60610. Phone: (312)280-7168.

CHANGE OF ADDRESS—POSTMASTER, send all address changes for the ARCHIVES OF SURGERY to Caryl L. Wertheimer, Director of Fulfillment, 535 N Dearborn St, Chicago, IL 60610. Notification of address change must be made at least six weeks in advance, include both old and new addresses, a recent mailing label, and your new zip code.

ADVERTISING PRINCIPLES: Each advertisement in this issue has been reviewed and complies with the principles governing advertising in AMA scientific publications. A copy of these principles is available on request. The appearance of advertising in AMA publications is not an AMA guarantee or endorsement of the product or the claims made for the product by the manufacturer.

CONTENTS—Continued

The Desmoid Tumor: Not a Benign Disease 191
Mitchell C. Posner, MD; Man H. Shiu, MD; James L. Newsome, MD; Steven I. Hajdu, MD; Jeffrey J. Gaynor, PhD; Murray F. Brennan, MD, New York, NY
- Desmoid tumors are malignant soft-tissue neoplasms that require aggressive therapy.

Scar or Recurrent Rectal Cancer: Positron Emission Tomography Is More Helpful for Diagnosis Than Immunoscintigraphy 197
Peter Schlag, MD; Burkhard Lehner, MD; Ludwig G. Strauss, MD; Peter Georgi, MD; Christian Herfarth, MD, Heidelberg, Federal Republic of Germany
- All patients with increased uptake of flu-deoxyglucose F 18 by positron emission tomography had recurrent rectal cancer.

Prognostic Significance of Cellular Immunity to Autologous Breast Carcinoma and Glycoprotein 55 202
Maurice M. Black, MD; Reinhard E. Zachrau, MD; Roy H. Ashikari, MD, Valhalla, NY; Benjamin F. Hankey, ScD, Bethesda, Md
- Cellular immunity as measured by skin window reactivity to autologous breast cancer is prognostically favorable.

Photodynamic Therapy for Cutaneous and Subcutaneous Malignant Neoplasms 211
James S. McCaughan, Jr, MD; Jerry T. Guy, MD; William Hicks, MD; Leslie Laufman, MD; Thomas A. Nims, MD; John Walker, Columbus, Ohio
- Photodynamic therapy produced a complete response with no evidence of tumor in a number of patients.

Antioxidants vs Carotenoids: Inhibitors or Promoters of Experimental Colorectal Cancers 217
Thomas A. Colacchio, MD; Vincent A. Memoli, MD; Laurie Hildebrandt, Hanover, NH
- Ascorbic acid and alpha-tocopherol demonstrated a chemopreventive effect against induced murine tumors.

Plasma Ultrafiltration as Cancer Therapy 222
Alan Wile, MD, Orange, Calif
- Serum ultrafiltration therapy in six patients reduced their serum suppressor factors.

Endoscopic Ablation of Esophageal Malignancies With the Neodymium-YAG Laser and Electrofulguration 225
Hector R. Nava, MD; Marlys E. Schuh, MD; Raman Nambisan, MD; John L. Clark, MD; Harold O. Douglass, Jr, MD, Buffalo, NY
- Both techniques improved swallowing with mean survival for these patients of 11 months.

Are Complications in Intraoperative Radiation Therapy More Frequent Than in Conventional Treatment? 229
Douglas T. Cromack, MD; Michelle M. Maher, RN; Harald Hoekstra, MD, PhD; Timothy J. Kinsella, MD; William F. Sindelar, MD, PhD, Bethesda, Md
- No, complications are not more frequent with intraoperative radiation therapy!

The Influence of Natural Killer Cells in Neuroblastoma 235
John V. Reynolds, FRCS(I); Jian Shou, MD; Hoon Choi, MD; Robert Sigal, MD; Moritz M. Ziegler, MD; John M. Daly, MD, Philadelphia, Pa
- In vivo depletion of natural killer cells enhanced tumor growth and decreased survival in this animal model.

ORIGINAL ARTICLES

Pseudocysts in Chronic Pancreatitis: Surgical Results in 102 Consecutive Patients 240
Tuula Kiviluoto, MD; Leena Kivisaari, MD; Eero Kivilaakso, MD; Matti Lempinen, MD, Helsinki, Finland
- In patients with chronic pancreatitis and pseudocysts, internal drainage or resection produced the most satisfactory results.

Single-Dose Antibiotic Prophylaxis in Contaminated Abdominal Surgery 244
John C. Hall, FRACS, Perth, Western Australia; J. McK. Watts, FRACS, Lexi Press, RN, Bedford Park, South Australia; P. O'Brien, FRACS, Melbourne, Australia; J. Turnidge, FRACP, P. McDonald, FRACP, Bedford Park, South Australia
- In patients undergoing contaminated abdominal operations, a single dose of prophylactic antibiotic was as effective as an extended course of antibiotics.

Long-term Survival in Carcinoma of the Biliary Tract: Analysis of Prognostic Factors in 146 Resections 248
Kiyoaki Ouchi, MD; Seiki Matsuno, MD; Toshio Sato, MD, Sendai, Japan
- Following resection, 41% of patients with gallbladder cancer and approximately 23% of patients with bile duct cancer lived 5 years.

Follow-up of Patients With Aspirated Breast Cysts Is Necessary 253
Hisham Hamed, MD; Andrew Coady, MS; Murid A. Chaudary; Ian S. Fentiman, MD, London, England
- Reexamination six weeks following aspiration of a breast cyst is necessary.

THE WRONG STUFF?

For patients with no gut function, TPN is the right choice. But feeding only parenterally can cause gut atrophy and lead to physiologic compromise.[1] It has been estimated 80% to 85% of the patients traditionally placed on TPN can be managed by enteral methods alone.[2]

THE RIGHT STUFF

Because VIVONEX T.E.N. uses the gut, it protects the mucosal barrier and avoids intestinal atrophy that can lead to complications.[1] VIVONEX T.E.N. is clinically comparable to TPN,[3] plus it is the only leading enteral formula that contains the amino acid glutamine. And TPN doesn't contain glutamine, which animal studies have shown to be a key fuel for the small intestine[4] and to maintain the integrity of the intestinal villi and mucosal wall.[5,6]

VIVONEX®
T.E.N.

BETTER THAN TPN BECAUSE IT KEEPS THE GUT WORKING

WIDENING HORIZONS

ZANTAC INJECTION OFFERS THE WIDEST VARIETY OF DOSAGE FORMS TO MEET HOSPITAL NEEDS

ZANTAC® Injection
(ranitidine hydrochloride)

BRIEF SUMMARY

ZANTAC® Injection Premixed
(ranitidine hydrochloride)

The following is a brief summary only. Before prescribing, see complete prescribing information in ZANTAC® Injection/ZANTAC® Injection Premixed product labeling.
INDICATIONS AND USAGE: ZANTAC® Injection and ZANTAC® Injection Premixed are indicated in some hospitalized patients with pathological hypersecretory conditions or intractable duodenal ulcers, or as an alternative to the oral dosage form for short-term use in patients who are unable to take oral medication.
CONTRAINDICATIONS: ZANTAC® Injection and ZANTAC® Injection Premixed are contraindicated for patients known to have hypersensitivity to the drug.
PRECAUTIONS: General: 1. Symptomatic response to ZANTAC® therapy does not preclude the presence of gastric malignancy.
2. Since ZANTAC is excreted primarily by the kidney, dosage should be adjusted in patients with impaired renal function (see DOSAGE AND ADMINISTRATION). Caution should be observed in patients with hepatic dysfunction since ZANTAC is metabolized in the liver.
3. In controlled studies in normal volunteers, elevations in SGPT have been observed when H_2-antagonists have been administered intravenously at greater than recommended doses for five days or longer. Therefore, it seems prudent in patients receiving IV ranitidine at doses greater than or equal to 100 mg qid for periods of five days or longer to monitor SGPT daily (from day 5) for the remainder of IV therapy.
Laboratory Tests: False-positive tests for urine protein with Multistix® may occur during ZANTAC therapy, and therefore testing with sulfosalicylic acid is recommended.
Drug Interactions: Although ZANTAC has been reported to bind weakly to cytochrome P-450 in vitro, recommended doses of the drug do not inhibit the action of the cytochrome P-450-linked oxygenase enzymes in the liver. However, there have been isolated reports of drug interactions that suggest that ZANTAC may affect the bioavailability of certain drugs by some mechanism as yet unidentified (eg., a pH-dependent effect on absorption or a change in volume of distribution).
Carcinogenesis, Mutagenesis, Impairment of Fertility: There was no indication of tumorigenic or carcinogenic effects in lifespan studies in mice and rats at oral doses up to 2,000 mg/kg/day.
Ranitidine was not mutagenic in standard bacterial tests (*Salmonella, Escherichia coli*) for mutagenicity at concentrations up to the maximum recommended for these assays.
In a dominant lethal assay, a single oral dose of 1,000 mg/kg to male rats was without effect on the outcome of two matings per week for the next nine weeks.
Pregnancy: ***Teratogenic Effects: Pregnancy Category B:*** Reproduction studies have been performed in rats and rabbits at oral doses up to 160 times the human oral dose and have revealed no evidence of impaired fertility or harm to the fetus due to ZANTAC. There are, however, no adequate and well-controlled studies in pregnant women. Because animal reproduction studies are not always predictive of human response, this drug should be used during pregnancy only if clearly needed.
Nursing Mothers: ZANTAC is secreted in human milk. Caution should be exercised when ZANTAC is administered to a nursing mother.
Pediatric Use: Safety and effectiveness in children have not been established.
Use in Elderly Patients: Ulcer healing rates in elderly patients (65 to 82 years of age) treated with oral ZANTAC were no different from those in younger age groups. The incidence rates for adverse events and laboratory abnormalities were also not different from those seen in other age groups.
ADVERSE REACTIONS: Transient pain at the site of intramuscular injection has been reported. Transient local burning or itching has been reported with intravenous administration of ZANTAC®.
The following have been reported as events in clinical trials or in the routine management of patients treated with oral ZANTAC. The relationship to ZANTAC therapy has been unclear in many cases. Headache, sometimes severe, seems to be related to ZANTAC administration.
Central Nervous System: Rarely, malaise, dizziness, somnolence, insomnia, and vertigo. Rare cases of reversible mental confusion, agitation, depression, and hallucinations have been reported, predominantly in severely ill elderly patients. Rare cases of reversible blurred vision suggestive of a change in accommodation have been reported.
Cardiovascular: Rare reports of tachycardia, bradycardia, and premature ventricular beats.
Gastrointestinal: Constipation, diarrhea, nausea/vomiting, and abdominal discomfort/pain.
Hepatic: In normal volunteers, SGPT values were increased to at least twice the pretreatment levels in 6 of 12 subjects receiving 100 mg qid IV for seven days, and in 4 of 24 subjects receiving 50 mg qid IV for five days. With oral administration there have been occasional reports of reversible hepatitis, hepatocellular or hepatocanalicular or mixed, with or without jaundice.
Musculoskeletal: Rare reports of arthralgias.
Hematologic: Reversible blood count changes (leukopenia, granulocytopenia, and thrombocytopenia) have occurred in a few patients. Rare cases of agranulocytosis or of pancytopenia, sometimes with marrow hypoplasia, have been reported.
Endocrine: Controlled studies in animals and man have shown no stimulation of any pituitary hormone by ZANTAC and no antiandrogenic activity, and cimetidine-induced gynecomastia and impotence in hypersecretory patients have resolved when ZANTAC has been substituted. However, occasional cases of gynecomastia, impotence, and loss of libido have been reported in male patients receiving ZANTAC, but the incidence did not differ from that in the general population.
Integumentary: Rash, including rare cases suggestive of mild erythema multiforme, and, rarely, alopecia.
Other: Rare cases of hypersensitivity reactions (eg, bronchospasm, fever, rash, eosinophilia) and small increases in serum creatinine.
OVERDOSAGE: Information concerning possible overdosage and its treatment appears in the full prescribing information.
DOSAGE AND ADMINISTRATION: (See complete prescribing information in ZANTAC® Injection/ZANTAC® Injection Premixed product labeling.)
Dosage Adjustment for Patients with Impaired Renal Function: On the basis of experience with a group of subjects with severely impaired renal function treated with ZANTAC, the recommended dosage in patients with a creatinine clearance less than 50 ml/min is 50 mg every 18 to 24 hours. Should the patient's condition require, the frequency of dosing may be increased to every 12 hours or even further with caution. Hemodialysis reduces the level of circulating ranitidine. Ideally, the dosage schedule should be adjusted so that the timing of a scheduled dose coincides with the end of hemodialysis.
HOW SUPPLIED: ZANTAC® Injection, 25 mg/ml, containing phenol 0.5% as preservative, is available as follows:
NDC 0173-0362-38 2-ml single-dose vials (Tray of 10)
NDC 0173-0363-39 10-ml multi-dose vials (Singles)
NDC 0173-0363-00 40-ml Pharmacy Bulk Packages (Singles)
NDC 0173-0362-00 2-ml single-dose, prefilled, disposable syringes (Singles)
Store below 30°C (86°F). Protect from light.
ZANTAC® Injection Premixed in 0.45% Sodium Chloride, 0.5 mg/ml, is available as a sterile premixed solution for IV administration in 100-ml single-dose flexible plastic containers (NDC 0173-0407-00). It contains no preservatives.
Exposure of pharmaceutical products to heat should be minimized. Avoid excessive heat. Protect from freezing. It is recommended that the product be stored at room temperature (25°C); however, brief exposure up to 40°C does not adversely affect the product.

What will you tell her about screening mammography?

Many of your patients will hear about screening mammography through a program launched by the American Cancer Society and the American College of Radiology, and they may come to you with questions. What will you tell them?

We hope you'll encourage them to have a screening mammogram, because that, along with your regular breast examinations and their monthly self examinations, offers the best chance of early detection of breast cancer, a disease which will strike one woman in 10.

If you have questions about breast cancer detection for asymptomatic women, please contact us.

HIGH STANDARDS

The AMA's Ninth Annual Health Reporting Conference featuring TV/Radio Reporting and Spokesperson Training

April 13-16, 1989
Boston, Massachusetts

This conference is for physicians now on the air and for those who wish to break into broadcasting. Workshops are designed to provide skills enhancement for physician broadcasters and physician spokespersons at all levels. Health Reporting Conference training enables physician broadcasters and spokespersons to achieve and maintain high standards as medical reporters and spokespeople.

Workshops offer:
- —Hands-on television and radio studio experience
- —Broadcast writing, production and videotape editing workshops
- —Interviewing techniques
- —How to break into broadcasting, cable or narrowcasting
- —Voice training, make-up, contract negotiations
- —Platform speaking skills

A Unique Opportunity for
- —Networking
- —Critiques
- —Peer discussions

Fee Information
Fees: $590/AMA Members
$750/Non-Members
$200/Residents, Students
$250/Optional Day

Register for speakers training, beginning, intermediate or advanced broadcasting courses. Electives are open to all participants. Complete registration information is available by calling: 312/645-5102.

Portland, Oregon

GENERAL SURGEON—Excellent opportunity for Board Certified or Eligible general surgeon in large multispecialty group in Pacific Northwest. Immediate position available in 23-member surgery department in early or mid-1988. Group provides comprehensive medical care to 330,000 members of Kaiser Permanente in Oregon and Washington. Excellent salary and benefits, with opportunity to become shareholder after two years. Direct inquiry and c.v. to: Regional Medical Director, Northwest Permanente, P.C., 3600 N. Interstate Avenue, Portland, OR 97227.

FLORIDA, OKLAHOMA

General Surgery Opportunities

FLORIDA: Gainesville-based regional multi-hospital Healthcare System has immediate need for BE/BC general surgeons. Paid malpractice, salary guarantee, office space, moving expenses, others.

OKLAHOMA: BE/BC general surgeon needed to join multi-specialty group. Fee-for-service practice. Progressive, thriving, family oriented community. Excellent income potential and relocation package.

MINORITY MEDICAL RESEARCH FELLOWSHIPS

The Minority Medical Faculty Development Program, sponsored by The Robert Wood Johnson Foundation, has up to eight new positions available beginning in 1990. The program offers four-year postdoctoral research fellowships to physicians from underrepresented minority groups (blacks, Mexican Americans, native Americans, and mainland Puerto Ricans) who have demonstrated superior academic and clinical skills and who are committed to careers in academic medicine and biomedical research. Each fellow selected will receive an annual stipend of up to $50,000 and a $25,000 annual grant toward support of research activities.

In addition to the above eligibility requirements, applicants must be U.S. citizens and have completed their formal clinical training by the time of entry into the program.

Applications for appointment in 1990 must be submitted by April 3, 1989. Interviews with selected applicants will be carried out in July 1989, and successful candidates will be notified in December 1989.

For further information and application materials, contact: Harold Amos, PhD, Director, Department of Microbiology and Molecular Genetics, Harvard Medical School, 25 Shattuck Street, Boston, MA 02215. 617/732-1947.

Instructions for Authors

Manuscripts are to be sent by first-class mail to the Editor, Claude H. Organ, Jr, MD Professor, Dept of Surgery, University of California–Davis, East Bay 1411 E 31st St, Oakland, CA 94602. The procedures listed must be followed carefully and all materials requested must be enclosed for prompt review and consideration for publication in the *Archives of Surgery*. Use the checklist to ensure completeness.

Manuscript Preparation.—*The original typescript and two high-quality copies* of the entire manuscript must be submitted, including copies of all illustrations, legends, tables, and references. All copy, including references, legends, and tables, must be typed double-spaced on 8½ × 11-in, heavy-duty white bond paper. Margins must be at least 1 in. If a word processor is used, do *not* use justified right margins.

Abstract.—*Submit an abstract* (135-word maximum) of the manuscript, which must include a statement of the problem, methods of study, results, and conclusions. The synopsis-abstract replaces a summary or conclusions.

Copyright.—*A copyright release* form signed by *all* authors of manuscripts, brief communications, and correspondence is required by the Copyright Revision Act of 1976. The following statement, dated and signed by all authors, may be used: **"In consideration of the American Medical Association's taking action in reviewing and editing my submission, the author(s) undersigned hereby transfers, assigns, or otherwise conveys all copyright ownership to the AMA in the event that such work is published by the AMA."**

Financial Interest.—List all affiliations with or financial involvement in any organization or entity with a direct financial interest in the subject matter or materials of the research discussed in the manuscript (eg, employment, consultancies, stock ownership). All such information will be held in confidence during the review process. Should the manuscript be accepted, the Editor will discuss with the author the extent of disclosure appropriate for publication.

References.—*References* should be listed in *consecutive numerical order* as they are cited in the text, *not alphabetically*. Once a reference is cited, all subsequent citations should be to the original number. All references must be cited in the text or tables. Unpublished data and personal communication may not be listed as references. References to journal articles should include (1) authors, (2) title, (3) journal name as abbreviated in *Index Medicus*, (4) year, (5) volume number, and (6) inclusive page numbers—in that order. References to books should include (1) authors, (2) chapter title, if any, (3) editor, if any, (4) title of book, (5) year, (6) city, and (7) publisher. Volume and edition numbers, specific pages, and name of translator should be included when appropriate. The author is responsible for the accuracy and completeness of the references and for their correct text citation.

Author Responsibility.—One author must be designated *corresponding author*, with his or her address and telephone number provided. All correspondence and copy editing are sent to this author. The corresponding author will receive an edited typescript rather than galley proofs for approval. The authors are responsible for all statements in their work, including changes made by the copy editor. Order reprints at the time the typescript is returned after editorial processing. Specify the address to which requests for reprints should be sent.

Titles.—*The title* must be *short*, specific, and clear. It cannot exceed 42 characters per line, including punctuation and spaces, and is limited to two lines. The title page should include the full names and academic affiliations of all authors. If the manuscript was presented at a meeting, indicate the name of the organization, the place, and the date on which it was read.

SI Units.—Use Système International (SI) measurements throughout the manuscript.

Illustrations.—Use only illustrations that clarify and augment the text. Submit illustrations in triplicate, unmounted and untrimmed. Do not send original artwork. Send high-contrast glossy prints (not photocopies). Figure number, name of senior author, and arrow indicating "top" should be typed on a gummed label and affixed to the back of each illustration. All lettering must be legible after reduction to column size. Artwork submitted for publication may be relettered to achieve uniformity of lettering style throughout the journal. Illustrations should preferably be in a proportion of 5 × 7 in. *Color illustrations* are accepted for publication if the editors believe that color will add significantly to the published manuscript. The ARCHIVES will pay only part of the expense of color reproduction and printing color illustrations. The author's share of the expense is $400 for up to six square finished illustratons that can be arranged on a one-page layout. Any additional illustrations or special effects will be billed to the author at cost. Positive color transparencies (35-mm preferred) must be submitted for an evaluation. Do not send color prints unless accompanied by original transparencies.

CHECKLIST FOR AUTHORS

Send:

- Three copies of manuscript.
- Three copies of synopsis-abstract.
- Three copies of attached photographs, legends, tables, and/or illustrations clearly marked as described in the instructions.
- A copyright release statement signed by *all* authors.
- The address and telephone number of the designated corresponding author.
- Send to Claude H. Organ, Jr, MD
  Archives of Surgery
  Professor, Dept. of Surgery
  University of California–Davis, East Bay
  1411 E 31st St
  Oakland, CA 94602
- Use sufficient postage.

Legends.—*Legends* must be typed double-spaced, beginning on a separate sheet of paper. Length is limited to a maximum of 40 words.

Tables.—Each table must be typed double-spaced, including all headings, on a separate sheet of 8½×11-in paper. Do not use larger-size paper. If a table must be continued, use a second sheet and repeat all heads and stubs. Each table must have a title.

Manuscript Acceptance.—Manuscripts are received with the understanding that they *are not* under simultaneous consideration by another publication. Accepted manuscripts become the permanent property of the ARCHIVES and may not be published elsewhere without permission from the publisher (AMA).

OTHER INFORMATION

Brief Clinical Notes.—The ARCHIVES welcomes the submission of Brief Clinical Notes for review. These are generally reports of cases that provide a new or unique contribution and are to consist of no more than 400 words, two references, and one illustration. The synopsis-abstract may not exceed 80 words.

Correspondence and Brief Communications.—The Editor is pleased to receive letters that pertain to material published in the ARCHIVES as well as brief communications concerning other matters of interest to our readers. An interesting case may be published as a brief communication. Such contributions should be 250 words or less, typewritten, double-spaced without an abstract, and clearly marked "for publication." No more than two references are permitted and illustrations or tables are acceptable only when essential to the message.

News and Announcements.—Brief notices may be submitted of meetings, seminars, or symposiums that are of interest to surgeons.

Acknowledgments.—Illustrations from other publications must be acknowledged. Include the following when applicable: authors, title of article, title of journal or book, volume number, pages, month and year. The publisher's permission to reprint must be submitted to the ARCHIVES when the manuscript has been formally accepted.

Statistical Review.—Manuscripts containing statistical evaluation should include the name and affiliation of the statistical reviewer.

Informed Consent.—Manuscripts reporting the results of experimental investigations on human subjects must include a statement to the effect that informed consent was obtained after the nature of the procedure(s) had been fully explained.

Reference to Patients.—Patients should be referred to by number or, in anecdotal reports, by fictitious given names. Real names or initials must not be used in the text, tables, or illustrations.

Photographic Consents.—A letter of consent must accompany all photographs of patients in which a possibility of identification exists. It is *not* sufficient to simply cover the eyes to mask identity.

AMA Manual of Style.—This 1988 edition, formerly the *Manual for Authors & Editors*, is available from Williams & Wilkins, 428 E Preston St, Baltimore, MD 21202. Single copy price: $24.95. A shipping charge is added on all orders not prepaid. If additional ordering information is needed, or to order by telephone, call 1-800-638-0672.

SQUIBB

At risk for aminoglycoside toxicity:

The elderly.

AZACTAM—safer than aminoglycosides for elderly patients*

For a variety of reasons, including their often debilitated condition and serious underlying diseases, elderly patients have been reported to be at increased risk for aminoglycoside-associated toxicities.[1] AZACTAM represents a safer alternative for the treatment of gram-negative infections in these patients, an alternative that is free from the risks of nephrotoxicity† and ototoxicity.[2-5]

AZACTAM—the first monobactam—as effective as the aminoglycosides

In addition to its increased margin of safety, AZACTAM offers clinical and microbiological effectiveness equal to aminoglycosides in the treatment of gram-negative infections, such as peritonitis, intraabdominal abscess, and gangrenous appendicitis.[6-8] Its bactericidal activity is well suited for monotherapy when a susceptible gram-negative pathogen has been identified and is an ideal complement to gram-positive or anaerobic agents when empirical therapy is indicated.

**Dosage adjustment, based on estimated creatinine clearance, may be necessary in elderly patients.*
†Demonstrated in animal studies and in human volunteer studies. In clinical trials involving 4,570 subjects, transient elevations in serum creatinine were rarely observed.

For a discussion of INDICATIONS AND USAGE (including susceptible organisms), CONTRAINDICATIONS, WARNINGS, PRECAUTIONS, and ADVERSE REACTIONS, please consult brief summary on the following page.

The logical alternative to aminoglycosides

Azactam® instead.

aztreonam

The logical alternative to aminoglycosides

Azactam® instead.

aztreonam

AZACTAM® FOR INJECTION
Aztreonam For Injection

DESCRIPTION—AZACTAM (aztreonam, Squibb) is the first member of a new class of antibiotics classified as monobactams. AZACTAM is a totally synthetic bactericidal antibiotic with activity against a wide spectrum of gram-negative aerobic pathogens. The monobactams, having a unique monocyclic beta-lactam nucleus, are structurally different from other beta-lactam antibiotics.

AZACTAM For Injection is a sterile, nonpyrogenic, sodium-free, white to yellowish-white lyophilized cake, containing approximately 780 mg arginine per gram of aztreonam for intramuscular or intravenous use following constitution. Aqueous solutions of the product have a pH in the range of 4.5-7.5.

INDICATIONS AND USAGE—Before initiating treatment with AZACTAM, appropriate specimens should be obtained for isolation of the causative organism(s) and for determination of susceptibility to aztreonam. Treatment with AZACTAM may be started empirically before results of the susceptibility testing are available; subsequently, appropriate antibiotic therapy should be continued.

AZACTAM For Injection is indicated for the treatment of the following infections caused by susceptible gram-negative microorganisms: **Urinary Tract Infections** (complicated and uncomplicated), including pyelonephritis and cystitis (initial and recurrent) caused by *Escherichia coli, Klebsiella pneumoniae, Proteus mirabilis, Pseudomonas aeruginosa, Enterobacter cloacae, Klebsiella oxytoca**, *Citrobacter* species* and *Serratia marcescens**. **Lower Respiratory Tract Infections,** including pneumonia and bronchitis caused by *Escherichia coli, Klebsiella pneumoniae, Pseudomonas aeruginosa, Haemophilus influenzae, Proteus mirabilis, Enterobacter* species and *Serratia marcescens**. **Septicemia** caused by *Escherichia coli, Klebsiella pneumoniae, Pseudomonas aeruginosa, Proteus mirabilis**, *Serratia marcescens** and *Enterobacter* species. **Skin and Skin-Structure Infections,** including those associated with postoperative wounds, ulcers and burns caused by *Escherichia coli, Proteus mirabilis, Serratia marcescens, Enterobacter* species, *Pseudomonas aeruginosa, Klebsiella pneumoniae,* and *Citrobacter* species*. **Intra-abdominal Infections,** including peritonitis caused by *Escherichia coli, Klebsiella* species, including *K. pneumoniae, Enterobacter* species including *E. cloacae**, *Pseudomonas aeruginosa, Citrobacter* species* including *C. freundii** and *Serratia* species* including *S. marcescens**. **Gynecologic Infections,** including endometritis and pelvic cellulitis caused by *Escherichia coli, Klebsiella pneumoniae**, *Enterobacter* species* including *E. cloacae**, and *Proteus mirabilis**.

AZACTAM is indicated for adjunctive therapy to surgery in the management of infections caused by susceptible organisms, including abscesses, infections complicating hollow viscus perforations, cutaneous infections and infections of serous surfaces. AZACTAM is effective against most of the commonly encountered gram-negative aerobic pathogens seen in general surgery.

Concurrent Therapy—Concurrent initial therapy with other antimicrobial agents and AZACTAM is recommended before the causative organism(s) is known in seriously ill patients who are also at risk of having an infection due to gram-positive aerobic pathogens. If anaerobic organisms are also suspected, therapy should be initiated using an antianaerobic agent concurrently with AZACTAM. Certain antibiotics (e.g., cefoxitin, imipenem) may induce high levels of beta-lactamase *in vitro* in some gram-negative aerobes such as *Enterobacter* and *Pseudomonas* species, resulting in antagonism to many beta-lactam antibiotics including aztreonam. These *in vitro* findings suggest that such beta-lactamase inducing antibiotics not be used concurrently with aztreonam. Following identification and susceptibility testing, appropriate antibiotic therapy should be continued.

CONTRAINDICATION—Aztreonam is contraindicated in patients with known allergy to this antibiotic.

WARNINGS—Careful inquiry should be made for a history of hypersensitivity reaction to any antibiotic or other drugs. Antibiotics should be given with caution to any patient who has had some form of allergy, particularly to drugs. It is recommended that patients who have had immediate hypersensitivity reactions (e.g., anaphylactic or urticarial) to penicillins and/or cephalosporins should be followed with special care. If an allergic reaction to aztreonam occurs, discontinue the drug and institute supportive treatment as appropriate (e.g., maintenance of ventilation, pressor amines, antihistamines, corticosteroids). Serious hypersensitivity reactions may require epinephrine and other emergency measures.

PRECAUTIONS—General: In patients with impaired hepatic or renal function, appropriate monitoring is recommended during therapy. If an aminoglycoside is used concurrently with aztreonam, especially if high dosages of the former are used or if therapy is prolonged, renal function should be monitored because of the potential nephrotoxicity and ototoxicity of aminoglycoside antibiotics. The use of antibiotics may promote the overgrowth of nonsusceptible organisms, including gram-positive organisms and fungi. Should superinfection occur during therapy, appropriate measures should be taken.

Carcinogenesis, Mutagenesis, Impairment of Fertility—Carcinogenicity studies in animals have not been performed. Genetic toxicology studies performed *in vivo* and *in vitro* with aztreonam in several standard laboratory models revealed no evidence of mutagenic potential at the chromosomal or gene level. Two-generation reproduction studies in rats at daily doses up to 20 times the maximum recommended human dose, prior to and during gestation and lactation, revealed no evidence of impaired fertility. There was a slightly reduced survival rate during the lactation period in the offspring of rats that received the highest dosage, but not in offspring of rats that received five times the maximum recommended human dose.

Pregnancy—Pregnancy Category B: Aztreonam crosses the placenta and enters the fetal circulation. Studies in pregnant rats and rabbits, with daily doses up to 15 and 5 times, respectively, the maximum recommended human dose, revealed no evidence of embryo- or fetotoxicity or teratogenicity. No drug induced changes were seen in any of the maternal, fetal or neonatal parameters that were monitored in rats receiving 15 times the maximum recommended human dose of aztreonam during late gestation and lactation. There are no adequate and well-controlled studies in pregnant women. Because animal reproduction studies are not always predictive of human response, aztreonam should be used during pregnancy only if clearly needed.

Nursing Mothers—Aztreonam is excreted in breast milk in concentrations that are less than 1% of concentrations determined in simultaneously obtained maternal serum; consideration should be given to temporary discontinuation of nursing and use of formula feedings.

Pediatric Use—Safety and effectiveness have not been established in infants and children.

ADVERSE REACTIONS—Local reactions such as phlebitis/thrombophlebitis following IV administration, and discomfort/swelling at the injection site following IM administration occurred at rates of approximately 1.9% and 2.4%, respectively. Systemic reactions (considered to be related to therapy or of uncertain etiology) occurring at an incidence of 1 to 1.3% include diarrhea, nausea and/or vomiting, and rash. Reactions occurring at an incidence of less than 1% are listed within each body system in order of decreasing severity: *Hypersensitivity*—anaphylaxis. *Hematologic*—pancytopenia, neutropenia, thrombocytopenia, anemia, leukocytosis, thrombocytosis. *Gastrointestinal*— abdominal cramps; rare cases of *C. difficile*-associated diarrhea or gastrointestinal bleeding have been reported. *Dermatologic*—purpura, erythema multiforme, urticaria, exfoliative dermatitis, petechiae, pruritus, diaphoresis. *Cardiovascular*— hypotension, transient ECG changes (ventricular bigeminy and PVC). *Respiratory*—one patient experienced flushing, chest pain, and dyspnea. *Hepatobiliary*—hepatitis, jaundice. *Nervous System*—seizure, confusion, vertigo, paresthesia, insomnia, dizziness. *Musculoskeletal*—muscular aches. *Special Senses*—tinnitus, diplopia, mouth ulcer, altered taste, numb tongue, sneezing and nasal congestion, halitosis. *Other*—vaginal candidiasis, vaginitis, breast tenderness. *Body as a Whole*—weakness, headache, fever, malaise.

Adverse Laboratory Changes—Those reported without regard to drug relationship during clinical trials were: *Hepatic*—elevations of AST (SGOT), ALT (SGPT), and alkaline phosphatase; signs or symptoms of hepatobiliary dysfunction occurred in less than 1% of recipients (see above). *Hemic*—increases in prothrombin and partial thromboplastin times, eosinophilia, positive Coombs test. *Renal*—increases in serum creatinine.

OVERDOSAGE—If necessary, aztreonam may be cleared from the serum by hemodialysis and/or peritoneal dialysis.

DOSAGE AND ADMINISTRATION—Dosage adjustments are recommended for patients with impaired renal function. In elderly patients, estimates of creatinine clearance should be obtained and appropriate dosage modifications made if necessary.

HOW SUPPLIED—AZACTAM For Injection (Aztreonam For Injection)—Lyophilized—is supplied in single-dose 15 mL vials containing **500 mg,** or **1 g**/vial; in single-dose 30 mL vials containing **2 g**/vial; and in single-dose 100 mL intravenous infusion bottles containing **500 mg** or **1 g** or **2 g**/bottle.

Consult package insert before prescribing AZACTAM (aztreonam).

Only one H_2 antagonist controls pH for up to 12 hours on a single dose

PEPCID® I.V. (Famotidine, MSD) is indicated in some hospitalized patients with pathological hypersecretory conditions or intractable ulcers or as an alternative to the oral dosage forms for short-term use in patients who are unable to take oral medication.

The recommended dosage is 20 mg q12h. Dosing intervals may need to be prolonged or dosage reduced in patients with severe renal insufficiency (creatinine clearance <10 mL/min) to adjust for the longer elimination half-life of famotidine. All formulations of PEPCID are contraindicated in patients who are hypersensitive to any component of these products. The adverse reactions reported for Tablets PEPCID may also occur with PEPCID I.V. In addition, transient irritation at the injection site has been observed with PEPCID I.V.

ORAL SUSPENSION

Pepcid®

(Famotidine for Oral Suspension/MSD)

40 mg per 5 mL

INJECTION

Pepcid® IV

(Famotidine/MSD)

20 mg per 2 mL

Contraindications: Hypersensitivity to any component.

Precautions: ***General:*** Symptomatic response to therapy does not preclude the presence of gastric malignancy.

Patients with Severe Renal Insufficiency: Longer intervals between doses or lower doses may be needed in patients with severe renal insufficiency (creatinine clearance <10 mL/min) to adjust for the longer elimination half-life of famotidine (see Clinical Pharmacology and Dosage and Administration sections of Prescribing Information).

Information for Patients: The oral suspension should be shaken vigorously for 5 to 10 seconds prior to each use, and unused constituted oral suspension should be discarded after 30 days.

Drug Interactions: No drug interactions have been identified. Compounds tested in man include warfarin, theophylline, phenytoin, diazepam, aminopyrine, and antipyrine.

Carcinogenesis, Mutagenesis, Impairment of Fertility: In rats and mice given oral doses up to approximately 2,500 times the recommended human dose for active duodenal ulcer, there was no evidence of carcinogenic potential; at these doses in rats, fertility and reproductive performance were not affected. No evidence of a mutagenic effect was observed.

Pregnancy: *Pregnancy Category B*—There are no adequate or well-controlled studies in pregnant women. Use during pregnancy only if clearly needed.

Nursing Mothers: It is not known whether famotidine is secreted into human milk; however, it is secreted into the milk of lactating rats. A decision should be made whether to discontinue nursing or to discontinue the drug, taking into account the importance of the drug to the mother.

Pediatric Use: Safety and effectiveness in children have not been established.

Use in Elderly Patients: No dosage adjustment is required based on age but may be necessary in severe renal impairment (see Clinical Pharmacology section of Prescribing Information).

Adverse Reactions: The adverse reactions listed below have been reported during domestic and international clinical trials in approximately 2,500 patients. In the placebo-controlled clinical trials, the incidence of adverse experiences with PEPCID Tablets 40 mg at bedtime was similar to that with placebo.

Incidence Greater than 1%: The following adverse reactions have been reported to occur in more than 1% of patients on therapy with PEPCID in controlled clinical trials and may be causally related to the drug: headache (4.7%), dizziness (1.3%), constipation (1.2%), and diarrhea (1.7%).

Causal Relationship Unknown: The following other adverse reactions have been reported infrequently and within each category are listed in order of decreasing severity. The relationship to therapy with PEPCID has been unclear in many cases. *Body as a Whole*—Fever, asthenia, fatigue. *Cardiovascular*—Palpitation. *Gastrointestinal*—Cholestatic jaundice, liver enzyme abnormalities, vomiting, nausea, abdominal discomfort, anorexia, dry mouth. *Hematologic*—Thrombocytopenia. *Hypersensitivity*—Anaphylaxis, angioedema, orbital or facial edema, urticaria, rash, conjunctival injection. *Musculoskeletal*—Musculoskeletal pain, arthralgia. *Nervous System/Psychiatric*—Grand mal seizure; psychic disturbances including depression, anxiety, decreased libido, hallucinations; paresthesia; insomnia; somnolence. *Respiratory*—Bronchospasm. *Skin*—Alopecia, acne, pruritus, dry skin, flushing. *Special Senses*—Tinnitus, taste disorder.

The adverse reactions reported for PEPCID Tablets may also occur with PEPCID Oral Suspension or PEPCID I.V.; in addition, transient irritation at the injection site has been observed with PEPCID I.V.

AV block has been reported with other H_2-receptor antagonists, but not with famotidine.

Management of Overdosage: There is no experience to date with deliberate overdosage. Up to 640 mg/day have been given to patients with pathological hypersecretory conditions with no serious adverse effects. In the event of overdosage, treatment should be symptomatic and supportive. Unabsorbed material should be removed from the gastrointestinal tract, the patient should be monitored, and supportive therapy should be employed.

Dosage and Administration: ***Duodenal Ulcer:*** The recommended adult oral dosage for active duodenal ulcer is 40 mg h.s.; most patients heal within 4 weeks, and it is rarely necessary to use the full dosage for longer than 6 to 8 weeks. A regimen of 20 mg b.i.d. is also effective. For maintenance therapy, the recommended oral dosage is 20 mg h.s.

Benign Gastric Ulcer: The recommended adult oral dosage for active benign gastric ulcer is 40 mg h.s.

Pathological Hypersecretory Conditions (e.g., Zollinger-Ellison Syndrome, Multiple Endocrine Adenomas): The dosage varies with the individual patient; the recommended adult oral starting dosage is 20 mg q6h, but some patients may require a higher starting dosage. Dosages should be adjusted to individual patient needs and continued as long as clinically indicated; up to 160 mg q6h have been administered to some patients with severe Zollinger-Ellison syndrome.

Oral Suspension: The oral suspension may be substituted for tablets.

Directions for Preparing PEPCID Oral Suspension: Prepare suspension at time of dispensing. Slowly add 46 mL Purified Water. Shake vigorously for 5 to 10 seconds immediately after adding the water and immediately before use.

Stability of PEPCID Oral Suspension: Unused constituted oral suspension should be discarded after 30 days.

Intravenous Administration: In some hospitalized patients with pathological hypersecretory conditions or intractable ulcers or in patients who are unable to take oral medication, the recommended intravenous dosage is 20 mg q12h. For preparation of intravenous solutions for injection or infusion and for compatible diluents, please see Prescribing Information. Parenteral drug products should be inspected visually for particulate matter and discoloration prior to administration whenever solution and container permit.

Concomitant Use of Antacids: Antacids may be given concomitantly if needed.

Dosage Adjustment for Patients with Severe Renal Insufficiency: In patients with severe renal insufficiency (creatinine clearance less than 10 mL/min), the elimination half-life of famotidine may exceed 20 hours, reaching approximately 24 hours in anuric patients. Although no relationship of adverse effects to high plasma levels has been established, to avoid excess accumulation of the drug, the dosage may be reduced to 20 mg h.s. or the dosing interval may be prolonged to 36 to 48 hours as indicated by the patient's clinical response.

How Supplied: Tablets, containing 20 mg or 40 mg famotidine, with hydroxypropyl cellulose, hydroxypropyl methylcellulose, iron oxides, magnesium stearate, microcrystalline cellulose, starch, talc, and titanium dioxide as inactive ingredients, in unit-of-use bottles of 30 and unit-dose packages of 100; Oral Suspension, containing 40 mg famotidine per 5 mL after constitution with 46 mL Purified Water, with citric acid, flavors, microcrystalline cellulose and carboxymethylcellulose sodium, sucrose, and xanthan gum as inactive ingredients, and sodium benzoate 0.1%, sodium methylparaben 0.1%, and sodium propylparaben 0.02% added as preservatives, in bottles of 400 mg famotidine for constitution; Solution for intravenous injection, containing 10 mg famotidine per mL, with L-aspartic acid 4 mg, mannitol 20 mg, and Water for Injection q.s. 1 mL as inactive ingredients, and benzyl alcohol 0.9% added as preservative to the multidose vial, as 10x2-mL single-dose vials and as 4-mL vials.

Papers Read Before the Annual Meeting of the Society of Surgical Oncology, New Orleans, La, May 22 to May 25, 1988—Part II

Conservative Surgery and Radiation Therapy for Early Breast Cancer

Long-term Cosmetic Results

Mary Ann Rose, MD; Ivo Olivotto, MD; Blake Cady, MD; Clinton Koufman, MD; Robert Osteen, MD; Barbara Silver; Abram Recht, MD; Jay R. Harris, MD

• To evaluate the cosmetic outcome of conservative surgery (CS) and radiation therapy (RT) for early-stage breast cancer and its stability over time, we reviewed the records of 593 patients treated from 1968 to 1981. The breast appearance was scored as "excellent," "good," "fair," or "poor." Median follow-up was 76 months (range, 37 to 186 months). Cosmetic results were generally excellent or good. The percents of excellent, good, fair, and poor results at three years were 65%, 25%, 7%, and 3%, respectively. Patients not receiving adjuvant chemotherapy were more likely than those receiving chemotherapy to have excellent scores at five years (71% vs 40%). Tumor size also influenced cosmetic outcome: 73% of patients with T1 tumors vs 55% with T2 tumors had excellent scores at five years. Our results were stable over time: of 36 patients assessable at seven years whose cosmetic scores were good or excellent at three years, 34 (94%) continued to have good or excellent scores, and only two (5%) deteriorated to fair. We conclude that the cosmetic results achieved with CS and RT are good to excellent in approximately 90% of patients and that these results remain stable for at least seven years.

(*Arch Surg* 1989;124:153-157)

In recent years, the combination of conservative surgery (CS) and radiation therapy (RT) has gained increasing acceptance as an alternative to modified radical mastectomy for the treatment of early-stage breast carcinoma. The results of retrospective studies have shown excellent local tumor control with breast-conserving treatment,[1-6] and prospective randomized trials have demonstrated equivalent survival rates for patients treated with mastectomy or CS and RT.[7,8] In the setting of comparable local control and survival, the issue of long-term cosmetic outcome following the conservative approach has become increasingly important to the patient and to the treating physician.

Most reports of cosmetic results have shown that the majority of patients treated conservatively have a satisfactory breast appearance.[9-14] In an earlier report from our institution, 86% of patients had a good to excellent overall cosmetic score at five years.[9] Breast retraction, telangiectasia, and breast edema were the major factors determining the physician's long-term assessment of cosmetic outcome. These results are typical of those described by other researchers.[10-14]

The purpose of the present study was to enlarge and update our earlier observations to assess the long-term cosmetic outcome in patients treated with CS and RT. Our results indicate that good to excellent results are maintained over many years.

PATIENTS AND METHODS

Seven hundred thirty-three women with clinical stage I or II invasive breast carcinoma were treated with CS and RT at the Joint Center for Radiation Therapy, Boston, between July 1968 and December 1981. Fourteen women had bilateral tumors treated during that period for a total of 747 treated breasts. One hundred fifty-four patients were excluded from the analysis because cosmetic follow-up was not undertaken at this institution. A total of 593 patients were therefore assessable for the analysis of cosmetic outcome.

Follow-up was generally performed at six-month intervals after completion of treatment. Patients were censored from cosmetic follow-up at the time of local, distant, or opposite breast recurrence. The range of follow-up was 37 to 186 months, with a median of 76 months. The presence and severity of breast edema, retraction, fibrosis, telangiectasia, and arm edema were noted and a score of none, minimal, moderate, or severe was assigned by the physician for each factor on a standard follow-up form.[15] A score of "none" reflected no radiation sequelae; a score of "slight" reflected a change in the breast observable only by the trained eye; a score of "moderate" denoted an obvious change or defect in the breast; and a score of "severe" indicated a serious deformity or functional impairment, such as the need for a prosthesis to compensate for size difference between the breasts or the use of a sleeve to control arm edema. The overall cosmetic result was classified by the physician as excellent, good, fair, or poor. An "excellent" score was assigned when the treated breast looked essentially the same as the opposite breast. A "good" cosmetic score was used to describe minimal but identifiable effects of radiation on the treated breast. A "fair" cosmetic score was given when significant effects of radiation on the breast were noted. A "poor" cosmetic score was used to describe severe normal tissue sequelae. Both the scoring system for the individual radiation sequelae and that for the overall cosmetic outcome were subject to some physician bias and were not quantified by measurements of breast size, density, or nipple displacement. However these

scores did reflect both the degree to which these sequelae were obvious to the examiner and the degree of functional adjustment required by the patient. Several different physicians examined these patients over the time course of the study, a factor that also may have introduced some bias. In general, a physician's evaluation of a fair or poor result was harsher than the patient's perception of her result.

Results were plotted graphically by grouping observations into six-month time intervals. Not all patients were evaluated during every six-month interval. If more than one observation was made per patient per time interval, the worst score was used. The midpoint of each time interval was used in all curves; thus, individual observations ranged up to three months on either side of each time point. Analysis of results and comparisons between subgroups at specific time points of 3, 5, and 7 years were also undertaken.

The entire group of 593 patients was analyzed according to the following factors: (1) overall cosmetic score and time course, and the extent of (2) breast retraction, (3) breast edema, and (4) telangiectasia. The group was then subdivided and analyzed according to (1) whether or not an axillary dissection was performed, (2) use of adjuvant chemotherapy, (3) tumor size, (4) tumor location in the breast, and (5) age of the patient.

A description of our "standard" three-field technique to treat the breast and regional nodes has been previously reported.[16] The dose to the breast, and draining nodes when treated, was generally 4600 to 5000 cGy in 4½ to five weeks. Of 593 assessable patients, 550 (93%) received an additional boost (497 by iridium implant) to bring the total dose to 6000 cGy or more to the primary tumor area. Radiotherapy technical factors that had an impact on cosmetic outcome are addressed in a subsequent article.[17]

Axillary dissection was performed in 419 patients. In general the dissections were limited to level I and II lymph nodes to determine the need for adjuvant chemotherapy. "Complete" axillary dissections, including stripping of the axillary vein, were rarely performed in these patients.

One hundred thirty-four patients received some form of adjuvant chemotherapy, a factor previously reported to influence cosmetic outcome.[18,19] In 77 patients RT was completed before initiation of chemotherapy; in 49 patients RT and chemotherapy were delivered concurrently; seven patients received "sandwich" treatment that consisted of chemotherapy-radiotherapy-chemotherapy; and one patient completed her chemotherapy before beginning radiotherapy. The effect of sequencing of RT and adjuvant chemotherapy has been the subject of a separate report from our institution.[19]

Of the 593 patients, 340 had tumors measuring 2 cm or less (T1) and 253 had tumors between 2 and 5 cm (T2). It was not possible in this retrospective study to relate tumor size to breast size. Two hundred three patients had tumors located in "medial" portions of the breast, defined as the upper inner quadrant, the lower inner quadrant, and the 12-o'clock position. Three hundred twenty-seven patients had tumors located in "lateral" portions of the breast, defined as the upper and lower outer quadrants and at the 6-o'clock position. Fifty-five patients had tumors located centrally, defined as within 1 cm of the areola. In eight patients the primary location was unrecorded.

To determine the effect of age on cosmetic outcome, patients were divided into four age groups: age less than 35 years, 46 patients; age 35 to 50 years, 252 patients; age 51 to 65 years, 199 patients; and older than 66 years, 96 patients.

Statistical comparisons between groups and proportions were calculated at fixed time points using Fisher's exact test. P values of .05 or less were considered statistically significant.

RESULTS

The overall cosmetic scores for treated patients over time are shown in Fig 1. At three years, 62% of patients were scored as excellent, 26% as good, 9% as fair, and 3% as poor. At five years, 65% of patients had excellent scores, 25% good, 7% fair, and 3% poor. The results at seven years were similar to those at five years, with 54% scored as excellent, 24% as good, 15% as fair, and 7% having a poor score. To document further the stability of cosmetic results over time, we examined the outcome at seven years for two subsets of patients: those who had excellent scores at three years and those who had good scores at three years. Of 188 patients with excellent scores at three years, 25 were evaluated at seven years. Of those 25, 20 (80%) continued to have excellent results, four (16%) deteriorated to good, and one (4%) deteriorated to fair. Of 78 patients with good scores at three years, 11 were evaluated at seven years. Of those 11, six (55%) continued to have good scores, four (36%) improved to excellent, and one (9%) deteriorated to fair by seven years. No patient with either an excellent or good score at three years who was reevaluated at seven years had results that deteriorated to poor.

Overall cosmetic scores most closely paralleled the degree of breast retraction (Fig 2). Twenty-eight (78%) of 36 patients with fair or poor results three years after treatment showed evidence of moderate or severe retraction, while only 15 (6%) of 266 patients scored as good or excellent had moderate or severe retraction ($P<.0001$). The development of breast retraction generally occurred in the first three years and remained stable thereafter. At three years, 50% of 303 patients evaluated had no retraction, 35% had slight, 13% had moderate, and 2% had severe evidence of retraction. At seven years, 23 (43%) of 53 patients evaluated had no retraction, 21 (40%) had slight, seven (13%) had moderate, and two (4%) had severe retraction.

The development of telangiectasia occurred more slowly than breast retraction with the onset in most patients at 12 to 18 months (Fig 3). Moderate or severe telangiectasia was unusual, occurring in only 8% of patients at three and five years. At seven years eight (15%) of 53 assessable patients had moderate or severe telangiectasia (seven moderate, one severe).

Breast edema was most pronounced in the first year after treatment with 33% of patients exhibiting mild edema and 6% exhibiting moderate or severe edema at that time (Fig 4). Twenty percent of patients had some edema beyond three years that tended to resolve slowly between the fourth and eighth years. The incidence of breast edema was closely related to the use of axillary nodal dissection. Moderate and severe edema were significantly more common at one year in patients who underwent axillary dissection (8%) than in those who did not (<1%, $P=.002$). Beyond one year, the likelihood of persistent moderate and severe edema was close to zero; however, the likelihood of having any degree of breast edema was significantly greater after axillary dissection. Three years after treatment, 24% of patients who had an axillary dissection had some degree of breast edema compared with 11% of those who had no dissection ($P=.007$). At seven years the percentages were identical to those at three years but the difference was no longer statistically significant due to smaller numbers of evaluated patients.

The influence of the factors analyzed on cosmetic outcome is summarized in the Table. The use of an axillary dissection was associated with a decrease in the percentage of overall excellent outcomes in the first two years. There were significantly fewer excellent results six months after treatment among women who had an axillary dissection than among those who did not: 71% vs 86% ($P=.0005$). This difference persisted up to 18 months, at which time 75% of patients who did not have an axillary dissection had an excellent result compared with 61% of those treated with dissection ($P=.005$). Beyond two years, however, there was no difference in the overall cosmetic result. At five years, both groups had a 65% incidence of excellent results.

Fig 1.—Overall cosmetic results, 1968 to 1981. Numbers of patients assessable at 3, 5, and 7 years were 302, 179, and 54, respectively. Squares indicate percent excellent; circles, percent good; and triangles, percent fair/poor.

Fig 3.—Time course and extent of telangiectasia. Squares indicate percent none; circles, percent minimal; and triangles, percent moderate/severe.

Fig 2.—Time course and extent of breast retraction. Squares indicate percent none; circles, percent minimal; and triangles, percent moderate/severe.

Fig 4.—Time course and extent of breast edema. Squares indicate percent none; circles, percent minimal; and triangles, percent moderate/severe.

Patients who received adjuvant chemotherapy were significantly less likely to have excellent cosmetic scores and significantly more likely to have fair or poor scores at three and five years. Sixty-eight percent of patients who did not receive chemotherapy had excellent scores at three years compared with 37% of patients who did receive chemotherapy ($P<.0001$). At five years, the corresponding figures were 71% and 40%, respectively ($P=.001$). Conversely, 9% of patients who did not receive chemotherapy had fair or poor scores at three years compared with 24% of those who did receive chemotherapy ($P=.004$). At five years, these figures were 8% and 20%, respectively ($P=.09$). These differences persisted to seven years but the number of patients evaluated at that time was small.

Patients with tumors measuring 2 cm or smaller (T1) had a greater proportion of excellent cosmetic results compared with patients whose tumors were larger than 2 cm (T2). At three years, 70% of patients with T1 tumors were scored as having excellent results compared with 52% of patients with T2 tumors ($P=.002$). At five years, 73% of patients with T1 tumors had excellent results compared with 55% of those with T2 tumors ($P=.02$). When the comparison was restricted to patients who did not receive adjuvant chemotherapy, a similar trend was observed. At five years, 76% of patients with T1 tumors treated without chemotherapy had excellent results compared with 64% of patients with T2 tumors treated without chemotherapy (P=not significant [NS]). There were significantly more fair and poor results among patients with T2 tumors at both three and five years. Eighteen percent of patients with T2 tumors had fair or poor scores at three years compared with 8% of those with T1 tumors ($P=.01$). At five years, 16% of patients with T2 tumors had fair or poor scores compared with 6% of those with T1 tumors ($P=.05$). When the analysis was restricted to patients who received adjuvant chemotherapy, 14% of patients with T2 tumors had fair or poor scores at five years compared with 5% of patients with T1 tumors (P=NS).

Overall, the location of the primary tumor did not significantly influence the cosmetic outcome. At three years, 56% of patients with medial primary tumors had excellent outcomes compared with 66% of those with lateral tumors and 61% of those with central primary tumors (P=NS). At five years, the results were similar with 64%, 67%, and 56% having excellent results, respectively (all, P=NS). Patients with lateral primary tumors were somewhat less likely to have fair or poor results (10% and 8% at three and five years) than patients with medial lesions

(15% and 13% at three and five years) or central lesions (17% and 19% at three and five years).

When results were analyzed according to four age cohorts, no significant differences were seen in cosmetic outcome as an effect of age. At three years, 73% of patients younger than 35 years of age had excellent scores compared with 61% of women 35 to 50 years old, 63% of women 51 to 65 years old, and 61% of women 66 years old or older. At five years, the percents of excellent scores for these age groups were 75%, 64%, 67%, and 58%, respectively.

COMMENT

The results of this study with more patients and longer follow-up corroborate the earlier reports from our institution that 90% of patients treated with CS and RT have a good or excellent cosmetic outcome. Moreover, we have not observed detectable deterioration of the cosmetic outcome over time. Excellent scores at three years were likely to remain excellent and good results were more likely to become excellent than to deteriorate by seven years. Few patients were found to have an unsatisfactory cosmetic appearance even as late as seven years after treatment.

In the literature there has been controversy over the stability of the cosmetic results of CS and RT over time. Danoff et al[12] reported that two- to three-year follow-up was adequate to assess cosmetic outcome in patients treated with radiation alone but that longer follow-up was necessary in patients receiving chemotherapy. Ray and Fish[10] reported significant deterioration in the cosmetic results over the first three years after treatment, but they have published no subsequent report. Several centers in France have assessed their cosmetic results at five to ten years. Pierquin[2] reported that 90% (65/72) of patients with T1 lesions treated conservatively had very good cosmetic results with minimum five-year follow-up. Amalric et al[13] found that three quarters of 288 patients treated conservatively had modest or no radiation sequelae at ten years. Similarly, Calle et al[14] found that more than 95% of 99 assessable patients had acceptable cosmetic results at ten years. Our results corroborate these findings.

In this analysis, we did not intend to focus on the impact of chemotherapy on the cosmetic result since we have described this in detail elsewhere.[18,19] Our results continue to show that the use of adjuvant chemotherapy has a significant adverse effect on the cosmetic outcome, but that this is primarily true when the two treatment modalities are used simultaneously. We recently compared the cosmetic outcome of 41 patients treated with concurrent radiotherapy and chemotherapy (cyclophosphamide, methotrexate sodium, and fluorouracil in conventional doses) with that of 41 patients treated sequentially with the same regimen.[19] Among patients treated concurrently, 12% had an excellent, 58% had a good, 19% had a fair, and 11% had a poor cosmetic outcome two years after treatment. Among patients treated sequentially, 52% had an excellent, 38% had a good, 10% had a fair, and none had a poor cosmetic outcome at two years (difference in percent excellent, $P = .004$). Since adjuvant chemotherapy can have a major effect, especially when administered concurrently with radiation, we have attempted to adjust for it in this analysis to focus on other clinical factors. It is our current practice not to administer radiation and chemotherapy concurrently.

The various components of the cosmetic result—breast edema, retraction, and telangiectasia—evolved with different time courses. Breast edema occurred early (within the first year) and tended to resolve slowly. Breast retraction and telangiectasia occurred somewhat later but did not change significantly between the three- and seven-year marks. As previously reported both from our institution[9] and by Clarke et al,[20] the use of axillary dissection was associated with breast edema, at least in the immediate period after treatment. It is important to stress, however, that at five years the cosmetic result was not significantly influenced by the use of axillary node dissection, and in our view the benefits from such surgery far outweigh this transient cosmetic concern. Axillary dissection is useful in establishing more accurately the patient's prognosis, assuring local tumor control in the axilla, and simplifying the radiotherapy approach to treatment of the breast itself. It is our practice at this time to recommend a level I and II axillary dissection in all but elderly or debilitated patients.

We found that tumor size was an important factor in determining the cosmetic outcome. This is likely related to the necessity of more extensive breast surgery for larger tumors but may also reflect an unfavorable tumor to breast size ratio. In a separate report we have analyzed the technical factors of both the radiotherapy and the surgery to determine their impact on the cosmetic outcome.[17] This report clearly identifies the extent of breast surgery as a major factor influencing the cosmetic outcome. The results presented herein show the location of the tumor in the breast and the age of the patient to have no significant impact on the cosmetic outcome.

Our results provide support for the use of breast-conserving treatment by demonstrating satisfactory cosmetic results that appear to remain stable over time. While we are encouraged by the stability of the cosmetic results observed over the study time period, we realize that it is still possible to observe cosmetic deterioration over longer periods and we plan to continue to monitor our treated patients to assess this.

Discussion

Q Dr Rose, did you compare your group of patients who were treated with the iridium implantation with those who received no boost or electron boost?

A Yes we did. It will be the subject of an article that is coming out by Dr Olivotto concerning the technical aspects of treatment. When we compared patients who received iridium boosts with those who received no boost or electron boosts, 80% were excellent without a boost or with electron boosts vs only 60% who were excellent with iridium. At the present time, we are not using iridium implants routinely, and that is one of the reasons.

Q Did the size of breasts influence results?

A As you know, when you read a patient's chart and try to get this information, all you have is some subjective comment about large breasts or pendulous breasts and it is really difficult to quantitate that. In our experience, patients with very large breasts may have more retraction, but only if they are treated on a low-energy machine such as the 4-mV linear accelerator or with cobalt. If the appropriate energy machine is used, you should get a good cosmetic result. Those patients probably do less well in terms of symmetry and cosmetics with mastectomy and reconstruction, so it is all relative.

Q Could you comment on the correlation between posttreatment mammography and the clinical appearance of the breast?

A On mammography you may see diffuse increased density throughout the breast. You may also see skin edema. Usually the appearance stabilizes at about one year. We do not get mammograms until six months after treatment, but we believe that the mammographic appearance of the breast is beginning to stabilize at about one year and certainly by three years. It is not a normal-appearing mammogram, but I think that it is important in terms of follow-up of the patients. A mammographer has to be used to read mammograms of a radiated breast. You can see microcalcifications as a result of the implant. You can also see puffy popcorn-looking calcification as a result of fat necrosis.

Q What is the incidence of arm edema after the treatment?

A The incidence of arm edema after a level I and II dissection was only about 5% in patients who did not have the axilla and supraclavicular areas treated. We noticed that there is more arm edema and breast edema when the axilla and supraclavicular areas are treated. In recent years we have tended to get away from treating the third field. We let the surgeons dissect the axilla, and that is it for control in the axilla.

Q I see the major limitation of this treatment being that you cannot make the breast look any better than it started out looking. The most excellent results leave the breast looking identical, and in Atlanta, where I am working, that does not seem to be good enough for most women. We have seen requests for this treatment drop from 67% in 1982 to 20% in 1987. Do you see a trend like this?

A Absolutely not. A reconstructed breast, which is what you are talking about, is not a normal breast. Even if the breast does not look perfect, in my experience, women still generally prefer a breast that feels like a breast than a breast that looks perhaps a little bit better than our poor results.

Q I also want to ask about breast size. I know you said that you did not have that information, but some people have a subjective impression that the small breast does not do as well with radiation because, since the dose is fairly uniform regardless of the size of the breast, the skin changes are more intense. I wanted to ask you if you had any subjective impression about that? Others, for instance the Mayo Clinic, have reported much less satisfactory cosmetic results with radiation; the factor that they looked at was patient satisfaction. Did you have any information on patient satisfaction? Did you let the patient evaluate the cosmetic result rather than the physician?

A Yes. A point that I would like to make is that the cosmetic outcome really depends on the technique used. We are treating 400 new breast cases per year. The technique has gone through incredible refinements over the last 20 years. I do not see any difference at this time related to breast size, because the machine on which we treat the patient is chosen for that particular patient's breast size, so that we do not have these problems of more dose to the skin of smaller breasts and more dose to the subcutaneous tissue of larger breasts. We make every effort to avoid that problem by treating the patient on the right machine. Second, we tried to score patient satisfaction, but with a chart review it is very difficult to get a sense of that. Also, I think that there is a range of levels of patient satisfaction. However, in general it is fair to say that the physicians have been more critical of the results than have the patients themselves.

Local Recurrent Mammary Carcinoma Failing Multimodality Therapy

A Solution

Patricia M. McCormack, MD; Manjit S. Bains, MD; Michael E. Burt, MD, PhD; Nael Martini, MD; Ted Chaglassian, MD; David A. Hidalgo, MD

• Chest wall recurrence following radiation and hormonal therapy is an uncommon but serious and disabling condition. A chest wall ulcer secondary to treatment for recurrence also presents the same dilemma. Over the past 35 years, the Thoracic Service at our institution has treated 35 patients for these problems by surgical resection and reconstruction. Eight patients were seen after the first recurrence, six after the second, ten after the third, and ten after the fourth. One patient had chest wall resection with mastectomy when recurrence followed radiation therapy. Following resection of the tumor, 21 patients had reconstruction using mesh or a mesh "sandwich." There were no operative deaths and no respirator need. Twenty patients are alive from five to 120 months, with a median of 50 months. One of 35 patients had chest wall rerecurrence. Surgical resection of recurrent mammary carcinoma resistant to all other therapy is a viable alternative for both palliation and cure.

(*Arch Surg* 1989;124:158-161)

Local recurrence following initial treatment of primary operable mammary carcinoma varies from 1% to 2% for stage I to 10% to 12% for stage II. Major factors relating to relapse include type and extent of operation and the status of the lymph nodes.[1,2] Factors of lesser importance are the size and histologic grade of the primary tumor, the presence of invasion of the skin, and the length of free interval since primary treatment.[3-5] Hormone receptor status as a factor remains equivocal.[6] With the recent change to less radical surgery, an increase in local recurrence rates is being observed.

Postoperative radiation therapy decreases the incidence of local recurrence in high-risk patients but does not increase the overall cure rate.[7,8] Adjuvant chemotherapy *alone* does not decrease the incidence of local recurrence.[9]

Read before the Annual Meeting of the Society of Surgical Oncology, New Orleans, May 23, 1988.

Reprint requests to 1275 York Ave, New York, NY 10021 (Dr McCormack).

Local recurrence of tumor on the chest wall is usually treated with simple excision, where possible, followed by radiation therapy and chemotherapy in the presence of metastatic disease. In most instances, although specific percentages are not available, this suffices to control the tumor. There is a small group of patients, however, in whom the recurrence is not eradicated. This is usually related to tumor invasion of the underlying bony structures. These are the patients who need excision of the involved areas of the chest wall for control of the recurrent disease.

A second subgroup includes the patients who develop an ischemic ulceration following surgery and radiation therapy. These ulcerations can also be excised in a similar manner with equally good results.

SUBJECTS, MATERIALS, AND METHODS

From 1954 to 1987 the Thoracic Service at Memorial Sloan-Kettering Cancer Center, New York, performed 250 chest wall resections for tumor. Thirty-five of these were for mammary carcinoma, locally recurrent. The pathology material and patient charts were reviewed. The data were analyzed and results are presented herein.

Locally recurrent breast cancer for the purpose of this study is defined as the reappearance of cancer in the ipsilateral breast, the skin of the chest wall, or the parasternal area in the internal mammary lymph node chain.

The goal of the surgery is to resect all tumor with clear margins and to reconstruct the chest wall to provide physiologic integrity and a normal outward appearance, as most patients have already had radiation therapy to the area of recurrence. The blood supply to the skin of this area is compromised. This must be considered in the planning of skin and soft-tissue replacement. The plastic surgeon is consulted preoperatively to plan the most appropriate method for replacement of soft tissue and skin to restore as closely as possible a normal external appearance.

An intact thoracic cage is a prerequisite for adequate respiration. Any defect 5 cm or smaller will usually not interfere with pulmonary function. However, a larger defect should be repaired with a rigid prosthesis to prevent a "flail chest" with resultant pulmonary compromise. A defect directly over the heart and great vessels also requires a rigid replacement to protect these vital structures from inadvertent contusion. Since 1974, we have used a polyethylene template (Marlex) mesh–methyl methacrylate composite for this replacement.[10,11] The advantages it offers are (1)

Fig 1.—Incision placed wide of recurrent tumor.

Fig 2.—Defect resulting from four-rib resection. Lung forms base of defect.

Fig 3.—Body of sternum and costal cartilages have been resected.

Fig 4.—Methyl methacrylate composite is spread over polyethylene template (Marlex) mesh.

ready availability in the operating room, (2) the ability to construct a prosthesis to fit any size defect with any contour, and (3) resistance to wound infections because of tissue ingrowth into the mesh interstices. No patient has needed respirator support with this prosthesis in place.

Chest wall resection included sternum alone in five patients, ribs alone in 11, sternum plus ribs in ten, and a wedge resection of the adherent lung in eight. One patient required a forequarter amputation for neurovascular invasion that resulted in a painful paralytic arm.

Repair of the resultant defect in the thoracic cage consisted of a mesh–methyl methacrylate composite in the majority of the patients (26 [74%] of 35). Polyethylene template mesh alone was used in four patients and no replacement was necessary in five patients.

Soft-tissue coverage was not necessary in five patients where adjacent skin involvement was minimal. Twenty patients had a myocutaneous flap raised and transferred to cover the rigid repair with a soft-tissue replacement. This has been the most frequent type of tissue transfer used in the past decade and the most successful. A free myocutaneous flap can also be used and gives an excellent result. The microvascular technique required for a free flap lengthens operating time but provides an alternative when lesser options are not possible. The site of origin of the flap was based on the size and location of the defect as well as prior surgical scars and radiation treatment portals. Twenty patients had a myocutaneous flap, six had skin alone, in four the opposite breast was used, and in five no soft tissue was needed.

There was one rerecurrence among the 35 resections. There were two major infections that required drainage and irrigation of the wound and extended the hospital stay two weeks. Twenty-eight percent (10/35) of the patients are alive with disease at a median survival time of 36 months, while an equal number of patients are free of disease at a median time of 52 months.

TECHNIQUE

Initially, the skin incision should be made 2 cm wider than any visible tumor. It is then deepened to the rib level (Fig 1). An interspace is entered below the known tumor recurrence and the pleural cavity is explored with a finger. Adherence of the lung and the depth and size of the tumor can be readily assessed. If tumor invasion into lung is found, the adherent lung is wedged, using a stapler, and removed en bloc with the specimen.

One normal rib above and below the involved rib(s) and a 5-cm clearance laterally are the bone resection margins (Fig 2). When the sternum is involved, it is recommended to remove a "sleeve" of sternum rather than a lateral portion only (Fig 3). The internal

Fig 5.—Mesh–methyl methacrylate composite sutured in place.

Fig 6.—Sliding flaps of both breasts bridged the soft-tissue defect.

mammary artery and intercostal neurovascular bundles are identified and secured under direct vision.

After the resection is complete, when hemostasis is secured and the chest tubes have been placed, a clean lap pad is placed over the defect, creating a red-on-white pattern illustrating the size and contour to be followed in making the new insert. A piece of mesh is placed over this, and the methyl methacrylate is spread on the mesh according to the pattern (Fig 4). A second layer of mesh is then placed on top of the methyl methacrylate. It takes five minutes to harden. During this time, the composite is shaped to assume the contour of the resected chest wall. Excess mesh is trimmed to allow an approximately 2-cm sewing ring. Any heavy nonabsorbable suture material can be used to secure the composite to the skeletal rim of the defect (Fig 5).

Fig 7.—Latissimus dorsi myocutaneous flap, after being tunneled under axilla, is placed on top of methyl methacrylate composite.

Fig 8.—Myocutaneous flap on sixth postoperative day.

The plastic surgeon then restores the soft-tissue deficit (Fig 6). Skin flaps or the remaining breast can be used when the cosmetic result is not paramount. The myocutaneous or free flaps give superior results and were used in the majority of our patients (Figs 7 and 8). The patient is ready to be discharged from the hospital between the seventh and tenth postoperative days.

RESULTS

The ages of the patients ranged from 28 to 72 years, with a median age of 55 years. One patient had chest wall resection included with the radical mastectomy when the tumor was found to involve the ribs. Eight patients had one recurrence, six had two recurrences, ten had three recurrences, and ten had four recurrences before chest wall resection was done. The disease-free interval from treatment of the primary tumor to the first local recurrence varied from one to 30 years. The median was six years.

Most recurrences are located in or near the operative scar. Eighty percent are apparent within five years after surgery, and the remainder occur within the first ten years. In our series, there was one recurrence 30 years later. This is rare.

Half of the patients with local recurrence have this as

the only evidence of their cancer. Twenty-five percent have had metastases elsewhere preceding the development of chest wall tumor and the other 25% will develop metastases within a few months of the chest wall resections.

COMMENT

Locally recurrent breast cancer should first be treated by one or any combination of the usual therapeutic modalities, namely, local surgery, radiation therapy, chemotherapy or hormonal therapy, or any appropriate combination of these.[8,9,12] If recurrence persists despite their use, chest wall resection presents an alternative treatment possibility.

The survival results of this procedure reflect the stage of the disease rather than the chest wall surgery. In patients with local recurrence as the only residual carcinoma, a median survival approaching five years was seen in this series. There were no operative deaths. The wound infections were managed with local care. A single patient had a tumor recurrence that was re-excised; however, the patient died six months later of overwhelming metastatic cancer.

Respirator support was not needed for any patient following recovery from anesthesia when a methyl methacrylate composite was used.

Chest wall resection had a role to play in intractable locally recurrent breast cancer. It offers significant palliation even in the presence of recurrent tumor elsewhere.

Discussion

Q I wonder if you could comment on the treatment of these patients after chest wall resection. I think most of us believe that this is a lethal sign and the probability of these patients dying of their disease shortly is quite high. How do you manage them postoperatively?

A It depends on whether they have evidence of any disease elsewhere.

Q Let's say they are free of disease elsewhere.

A Then they just get followed up expectantly.

Q Do you still use this technique for patients who have infected chest walls and in cases of ulcerated wounds on the chest wall?

A Yes we do, with the provision that preoperatively they get appropriate antibiotics and local wound care. Even if you get an infection that is superficial above the mesh sandwich, you can irrigate it without having to remove the sandwich. We have done this in the two instances related herein and in two since this report was written.

Q While at M. D. Anderson Hospital and Tumor Institute (Houston) we used that in patients who did not have infections, but I just used myocutaneous flaps in patients who did have infections, and I did not find any significant flail chests. We measured the preoperative and postoperative vital capacity and the forced expiratory volume at 1 s in a number of patients. Just using myocutaneous flaps for massive chest wall resections up to 450 cm^2, we were able to show there was no significant difference in the preoperative and postoperative pulmonary functions without any Richard's support for the chest wall.

A That is very interesting, thank you.

Q Can I ask you why you left using the mesh alone and went to the methyl methacrylate, because when we went to the stiffeners, we found that there was really no advantage, even with a very large chest wall deficit, over using polyethylene template and pulling it taut. I want to know why you abandoned the use of mesh alone and went to the stiffeners.

A One of the main reasons was cosmetic. With mesh alone, you are left with a flat chest. With polyethylene template mesh–methyl methacrylate composite you can shape it to the contour that you like. Frequently these patients are women who are very conscious of what they look like, particularly after mastectomy. We find that it is easy to use. If the patient is improved cosmetically, I think it is worth doing.

The Alveolar-Arterial Oxygen Gradient in Patients With Documented Pulmonary Embolism

David T. Overton, MD, Joseph J. Bocka, MD

It has been reported that the finding of a normal Pao_2 level on arterial blood gas analysis does not exclude the diagnosis of acute pulmonary embolism. We wished to determine whether a more thorough evaluation of the blood gases would prove more helpful; specifically, whether it is possible for a patient with acute pulmonary embolism to have a normal alveolar-arterial (A-a) oxygen gradient. We studied this question in a patient population in which the diagnosis was definitively made via pulmonary arteriography. Sixty-four patients met all study criteria. In these patients, the A-a gradient ranged from 11.6 to 83.9 mm Hg (mean, 41.8 mm Hg). In three patients, the A-a gradient was normal for age. We conclude that a normal A-a oxygen gradient does not exclude the diagnosis of acute pulmonary embolism, and should not preclude further diagnostic procedures if there is a high index of suspicion (*Arch Intern Med* 1988;148:1617-1619).

Extent of Lymph Node Dissection in Melanoma of the Trunk or Lower Extremity

Daniel G. Coit, MD, Murray F. Brennan, MD

• The extent of lymph node dissection necessary to optimize survival and minimize local recurrence in patients with melanoma of the trunk or lower extremity is not well defined. We reviewed the records of 420 patients undergoing superficial or combined superficial and deep groin dissection for melanoma. Prognosis depended on the extent of lymph node involvement rather than the extent of surgery performed. Node-positive patients undergoing elective lymph node dissection had an improved survival over those undergoing therapeutic lymph node dissection. In no subgroup of patients was more extensive lymphadenectomy associated with significant improvement in survival or alteration in pattern of recurrence. Dissection of the deep pelvic nodes in patients with melanoma appears to be of more prognostic than therapeutic value.

(*Arch Surg* 1989;124:162-166)

There are a number of issues that remain controversial in the management of the regional lymph nodes in patients with malignant melanoma. The role of elective lymphadenectomy (ELND) remains a matter of debate, polarized on the one hand by a number of retrospective reviews,[1-5] which suggest a survival advantage in high-risk patients, and on the other hand by two prospective randomized studies reported by Sim et al[6] and Veronesi et al,[7] which report no survival advantage in any subgroup of patients undergoing ELND over those offered therapeutic lymphadenectomy (TLND) when pathologic lymph nodes become clinically evident.

Furthermore, in patients with melanoma metastatic to or potentially metastatic to groin nodes, the extent of groin dissection necessary to achieve optimal locoregional control and survival is not well defined. Many investigators have suggested that the superficial inguinofemoral lymphadenectomy (SILND) is sufficient for patients with clinically and histologically negative groin nodes, reserving combined superficial and deep inguinofemoral and ileo-obturator lymphadenectomy (CILND) for patients with either clinically or histologically positive superficial groin nodes.[8-11] Others have suggested that deep pelvic node involvement is indicative of disseminated disease and that deep groin dissection does not have an impact on survival.[12]

We undertook our study to clarify the management of groin nodes in patients with melanoma of the trunk or lower extremities. We addressed such issues as the role of ELND and the extent of surgery necessary in these patients, with regard to both survival and patterns of recurrence.

PATIENTS AND METHODS

We reviewed the records of 420 patients with malignant melanoma of the trunk and lower extremities undergoing either SILND or CILND at Memorial Sloan-Kettering Cancer Center, New York, between 1974 and 1984. Elective lymphadenectomy during that period was generally recommended for patients with lesions that were Clark level III or deeper or had a Breslow thickness of 1.5 mm or more, and clinically negative nodes. Therapeutic lymphadenectomy was undertaken for palpable, clinically involved nodes in the absence of distant metastatic disease. Node dissection was defined as palliative if the patient had evidence of distant metastatic disease and the procedure was performed for locoregional control of disease only.

Because the period of study embraced an evolution in the assessment of the primary lesions, with Breslow thickness available only in the latter years, all patients' tumors were staged according to the current American Joint Committee on Cancer staging system (Table 1). Records were analyzed for patient age and sex, clinical and pathologic disease stage, extent of surgery, extent of nodal involvement, pattern of recurrence, and status at last follow-up. Intervals to recurrence and survival were calculated from the time of lymph node dissection to the time of recurrence or last follow-up, respectively. Survival curves were calculated, using the method of Kaplan and Meier.[13] Survival distributions were compared using the log rank test.[14] Patterns of recurrence were compared, using the χ^2 test.

There were 175 male patients and 245 female patients. The median age of the patients was 51 years (range, 15 to 94 years). The distribution of clinical and pathologic disease stages is shown in the following tabulation and in Table 2.

	Clinical Stage	Pathologic Stage
IA	8	10
IB	68	69
IIA	112	91
IIB	50	31
III	148	161
IV	34	58

As can be seen, the intent of operation was elective in 238 patients (57%), therapeutic in 148 patients (35%), and palliative in the remaining 34 patients (8%). An SILND was performed in 269 patients—191 elective, 62 therapeutic, and 16 palliative. A CILND was performed in 151 patients—47 elective, 86 therapeutic, and 18 palliative.

Pathologically positive nodes were recovered in 203 patients (48%), in 53 (22%) after ELND, in 119 (80%) after TLND, and in

Fig 1.—Survival by extent of lymph node involvement in 420 patients after groin dissection for melanoma.

31 (91%) after palliative lymphadenectomy.

Complete follow-up data were available for 415 patients (99%). The median follow-up of patients alive at the time of this review was 86 months. The median time to death in patients dying of disease was 20 months.

RESULTS

The estimated five-year survival was related to extent of lymph node involvement (Fig 1). For patients with histologically uninvolved nodes, the five-year survival was 80%. For patients with only positive superficial inguinofemoral nodes, the five-year survival was 37% (median, 36 months; $P<.001$ vs none). For patients with both superficial and deep nodes (iliac, obturator, or both) involved, the median survival was 12 months with only one patient in this series surviving five years ($P<.001$ vs superficial node involvement only).

In patients with negative nodes, there was no difference in survival between those undergoing SILND and those undergoing CILND (Fig 2). The trend favoring SILND in node-negative patients was not significant and correlated with prognostic variables of the primary lesions being slightly more favorable in the SILND group.

Elective Lymphadenectomy

Fifty-three (22%) of 238 patients undergoing ELND were found to have histologically positive nodes. A significant survival advantage was observed in these patients when compared with 119 patients undergoing TLND with histologically positive nodes (Fig 3), with a five-year survival of 53% (median, 64 months) in the former group vs a five-year survival of 31% (median, 32 months) in the latter group ($P<.005$).

Superficial nodes only were involved in 48 (91%) of these 53 patients. In these 48 patients, there was a trend toward a survival advantage after CILND (67%) compared with SILND (44%) (Fig 4), but this difference was not statistically significant ($P>.05$). Three patients undergoing elective CILND were found to have microscopic deep node involvement. Two of these patients died of disease at 32 and 59 months after lymphadenectomy, respectively, and one remains alive with intransit disease at 44 months after lymphadenectomy.

Therapeutic Lymphadenectomy

Of the 148 patients undergoing TLND, positive nodes were recovered in 119 (80%). In this group, the overall five-year survival was 31%, 37% for patients with only superficial nodal involvement (median, 39 months), and 5.6% for patients with superficial and deep nodal involvement (median, 12 months). One hundred nine patients undergoing TLND had only superficial nodes involved. The CILND conferred no survival advantage over SILND in this group of patients (38% vs 34%; median, 40 months for both groups; P, not significant) (Fig 5).

Palliative Lymph Node Dissection

Thirty-four patients underwent palliative lymphadenectomy for clinical stage IV disease. All patients in this group were dead of disease by 50 months after lymphadenectomy (median, 12 months). The extent of surgery had no impact on the length of survival in this group.

Patterns of Recurrence

The patterns of nodal recurrence are shown in Table 3. Recurrence was documented in 198 (47%) of 420 patients, in 97 (36%) of 269 patients after SILND, and in 101 (67%) of 151 patients after CILND ($P<.001$). Node-negative patients had recurrences more frequently after CILND than after SILND—12 (39%) of 32 vs 34 (18%) of 185, respectively ($P<.02$). This reflects the slightly worse prognostic characteristics of the primary lesions in the node-negative patients undergoing CILND. Node-positive patients had recurrences with equal frequency after either procedure—63 (75%) of 84 after SILND and 89 (75%) of 119 after CILND.

Nodal recurrence, defined as recurrence in the groin that was operated on, either superficial or deep, was observed as the first site of failure in 12 patients, 2.9% of

Fig 2.—Survival by extent of surgery in 217 patients with melanoma and histologically negative lymph nodes after superficial inguinal-femoral lymphadenectomy (SILND) vs combined superficial and deep inguinalfemoral and ileo-obturator lymphadenectomy (CILND).

Fig 4.—Survival by extent of surgery in patients with melanoma and histologically positive superficial lymph nodes only after elective superficial inguinalfemoral lymphadenectomy (SILND) vs combined superficial and inguinalfemoral and ileo-obturator lymphadenectomy (CILND).

all patients, and 6.1% of all patients who had recurrences. Nodal recurrence was seen as a component of the overall pattern of failure in 26 patients, 6.2% of all patients, and 13.1% of all patients who had recurrences. Nodal recurrence was no more common after SILND than after CILND, either as the first site of failure or as a component of the overall pattern of failure. This was true whether the nodes at the original lymphadenectomy were positive or negative.

Prediction of Deep Node Positivity

Clinical and pathologic factors of the 150 patients who underwent CILND were further analyzed to see what might predict deep node positivity. Factors that were important included positive Cloquet's node, the number of positive superficial nodes, the clinical stage of the patient's disease, and, of borderline significance, whether the superficial nodes were microscopically or macroscopically positive (Table 4). Factors that were not significant included site of the primary tumor and the sex and age of the patient.

Morbidity and Mortality

One patient in this series died after SILND, for an overall operative mortality of 0.24%. The median length of stay in the hospital was 13.5 days after SILND and 17 days after CILND. No attempt was made to define short-term or long-term morbidity, as estimates of these from retrospective reviews are notoriously conservative. Nonetheless, it is generally acknowledged that the complications after CILND are as great or, in most series, greater than those associated with SILND.[7,8,10,11]

COMMENT

It is quite clear that histologic involvement of groin nodes by malignant melanoma is associated with a guarded prognosis, with only 20% to 30% of patients surviving five years free of disease after aggressive surgery.[7,9-11,15] It is also apparent that survival correlates with extent of lymph node involvement: those patients with microscopic superficial node involvement fare better than those with grossly positive superficial nodes,[9,11,16] and survival with positive deep nodes is uniformly poor (Table 5). Less clear is the impact that more-extensive surgery has on improving the outcome in patients with melanoma metastatic or potentially metastatic to the groin nodes. In our study, there was no significant survival advantage in any subgroup of patients undergoing CILND when compared with those undergoing SILND.

Node-Negative Patients

In node-negative patients, the survival distributions were no different (Fig 2). This would imply that in the setting of histologically negative superficial nodes, the likelihood is small of microscopic spread confined to the deep nodes that could be encompassed by more extensive surgery. In fact, only one of the 150 patients undergoing CILND was found to have positive deep groin nodes with negative superficial groin nodes, and this patient died of systemic disease 44 months after lymphadenectomy. This low incidence of "skip metastases" reflects that reported by other investigators.[8-10] Furthermore, nodal recurrence in node-negative patients was no more common either as the first site of recurrence or as a component of the overall pattern of failure in patients undergoing SILND over those subjected to CILND.

Node-Positive Patients

In node-positive patients, no survival advantage of CILND over SILND could be demonstrated. When analyzed by intent of operation, survival distributions for

patients undergoing TLND were nearly identical for the two procedures. The same was true if only the superficial node–positive patients undergoing CILND, ie, a favorable subset of patients most likely to benefit from removal of microscopic deep nodal metastases, were compared with node-positive patients undergoing the more conservative operation.

Positive nodes were recovered in 53 (22%) of 238 patients undergoing ELND—6% of patients with clinical stage IB disease, 25% of patients with clinical stage IIA disease, and 42% of patients with clinical stage IIB disease (Table 2). The survival at five years in this group was 24% better than in the group of patients undergoing TLND with positive nodes. These data once again confirm the retrospective observations of other investigators[1-3,8-10] who advocate ELND in patients at risk for occult nodal metastases before they become clinically apparent.

This survival increment must be viewed in perspective, however. If we accept that the survival impact of ELND in node-negative patients is less important, then applying that 22% survival advantage to the 22% of patients undergoing ELND who are node-positive yields a net impact on survival of all patients undergoing ELND of about 5%. If this is so, it may be impossible, even in the current Intergroup Melanoma randomized trial, to prove that ELND has a role in the management of primary melanoma in patients at high risk for occult nodal metastases.

Nineteen patients underwent elective CILND for clinically negative groin nodes and were found to have only superficial nodes involved. There was a trend toward improved survival in this group when compared with patients undergoing elective SILND who were found to have superficial positive nodes (Fig 4), but this was not significant. This trend can be explained in part by the fact that, based on the predictive factors of number of positive superficial nodes and macroscopic appearance of the superficial nodes, some of the patients in the elective SILND group may have had positive deep nodes, thus adversely affecting survival in this group.

Significance of Deep Node Positivity

The reason that deep pelvic node dissection cannot be shown to improve survival lies in the very poor prognosis

of those patients in whom the deep nodes are positive. While there are a number of long-term survivors with positive deep nodes after CILND reported in the literature, the collective five-year survival is no more than 10% (Table 5). In this review, of 34 patients with histologically positive deep nodes, only two are alive, one with intransit disease 40 months after lymphadenectomy and one free of disease 102 months after lymphadenectomy. Of 23 patients with macroscopically positive deep nodal disease, 22 died of disease two to 46 months after lymphadenectomy. Of 11 patients with microscopic deep nodal disease, ten died of disease four to 59 months after lymphadenectomy. Of 19 patients who underwent therapeutic CILND for clinically positive nodes, 18 with positive deep nodes died of disease four to 44 months after lymphadenectomy. Three patients undergoing elective CILND were found to have microscopic positive deep nodes; two of these patients died of disease 32 and 59 months, respectively, after lymphadenectomy, and one patient is alive with intransit disease 44 months after lymphadenectomy. In summary, involvement of deep groin nodes in this series was associated with systemic spread of disease in at least 32 (94%) of 34 patients in whom it was found.

Nodal Recurrence

One of the arguments in support of CILND is that it will result in improved locoregional control, especially in patients with clinically positive nodes, avoiding the difficult problem of deep pelvic nodal recurrence. Data from our study do not support this position. It is of interest, however, that of the 13 patients in whom nodal recurrence was the first site of relapse, two (15%) are currently alive and free of disease at 42 and 146 months, respectively, after recurrence—one after surgery and one after chemotherapy and surgery.

CONCLUSION

A proportion of patients with melanoma metastatic to groin nodes have disease that is locoregional only and will be rendered long-term disease free by aggressive surgery. However, the ultimate prognosis appears to depend more on the extent of the disease than on the extent of surgery performed. Patients harboring occult metastases who undergo ELND have an improved chance of survival compared with those patients undergoing TLND for clinically positive nodes. Patients with only superficial nodes involved have a substantially better survival than those with positive superficial and deep nodes. In no subgroup of patients was more extensive lymphadenectomy associated with a significant improvement in survival or alteration in the pattern of recurrence in those patients who had recurrences. We conclude that dissection of the deep pelvic nodes in patients with melanoma may be more of prognostic than therapeutic value in the majority of patients.

Discussion

Q I do not think it can be as categorical as you stated that the deep node dissection does not offer suvival advantage, at least in our experience. We had 117 patients who had groin dissection, 56 of whom had positive nodes, and 43 patients had palpable nodes as well. Of these 43 patients who had palpable nodes, 18 (44%) also had deep inguinal nodes involved. In all the patients who had TLND, we performed a radical or ileo-inguinal node dissection, and the estimated five-year survival two years ago was 48% for patients who had only inguinal nodes involved and 30% for patients who had inguinal and deep nodes involved.

I have updated the survival for the 56 patients with positive nodes. All patients now have had at least a five-year follow-up, and the five-year survival for the patients who had only inguinal nodes involved was 42%. The five-year survival for the patients who had positive inguinal as well as deep nodes was 33%. Therefore, I think that we have to look at this issue more extensively because our experience differs from yours. I am not sure whether we see a different kind of population. The mean number of nodes involved in our patients with positive lymph nodes was 5.3, with a median of two positive nodes.

I feel, however, that it is important that a complete node dissection be performed in patients who have palpable nodes in the groin to realize the full potential of this operation. I think that there is a survival advantage with an ileo-inguinal node dissection, and not simply a diagnostic staging.

A One of the concerns that we had about your earlier report was the short median follow-up and the fact that only two of those patients with deep positive nodes were actually known to survive beyond five years. The fact that you are able to tell us today that 33% of those patients are alive and free of disease is an important addition.

Q You say the ELNDs seem to have a survival advantage of some 20 months over the TLNDs. Could it also be that you are comparing apples and oranges? Perhaps you are picking up the disease at two different times in its course so there is a greater time between treatment and death but death still happens in August 1988. If you left the patients alone they might have a 20-month period before they develop clinically positive nodes.

A I think that is a very good question, and the answer is very clearly no. It is not lead time bias for two reasons. First of all, we know that the median time from diagnosis to the development of clinically positive nodes is 16 months in this group of patients. We have looked at about 1000 patients to find these disease intervals. If this were a matter of lead time bias, what we would see is these two curves coming together, plateauing at the same survival, but we do not see that. We see a sustained survival advantage beyond ten years of follow-up. This is clearly not a phenomenon of lead time bias. We were very concerned about that, but I think this is clearly a sustained survival difference.

Hepatectomy Prolongs Survival of Mice With Induced Liver Metastases

Manuel H. Castillo, MD; Ralph J. Doerr, MD; Norman Paolini, Jr, MS; Stephen Cohen, PhD; Martin Goldrosen, PhD

• Resection of hepatic metastases from colorectal cancer has been shown to prolong survival in some patients. Whether this results from a reduction of tumor burden or is an indirect effect mediated by hepatectomy is questionable. Male C57BL/6Ros 8-week-old mice underwent ileocolic vein injection of a suspension of 0.3 mL of 2×10^5 viable liver-derived murine (MCA-38) colonic adenocarcinoma cells. This model produces hepatic metastases in all lobes of the liver. At 7, 14, or 21 days after tumor injection, mice were randomized to receive either 42% resection of the liver or laparotomy alone. Survival in the animals with hepatectomy was significantly prolonged when the hepatectomy was performed 14 or 21 days after tumor injection.

(*Arch Surg* 1989;124:167-169)

Liver metastases represent the most important cause of death for patients with colorectal cancer.[1] Laboratory data suggest that partial hepatectomy (HEP) might benefit this patient population by inducing an immune response capable of producing regression of micrometastases or by retarding progression of established macrometastases.[2]

Data regarding the effect of partial HEP on tumor systems are controversial. Both tumor progression and regression or disappearance of metastases have been reported following partial HEP.[2-4] A proved metastatic model using the ileocolic vein (ICV) was selected to study these observations.[5] Animals were injected with syngeneic liver-derived MCA-38 colonic adenocarcinoma cells. Liver metastases were successfully induced and partial HEP (42%) was performed on these tumor-bearing mice at 7, 14, and 21 days following ICV injection. In this study, we report our results on the effect of partial HEP on survival and the reliability of the ICV injection as an excellent metastatic model.

MATERIAL AND METHODS

Animals

Male C57BL/6Ros mice (West Seneca Laboratories, West Seneca, NY), 6 to 8 weeks old, were maintained on a standard mouse diet of pellets and water ad libitum.

Tumor Cells

The C57BL/6Ros tumor-bearing mice were killed and pinned to a dissecting board. Abdominal and chest walls were resected and HEP was performed. The liver was placed into a sterile Petri dish containing 10 mL of 0.25% trypsin–edetic acid (EDTA) maintained at 4°C. Tumor nodules were dissected from normal liver tissue using scalpel and fine-tissue forceps. The tumor was divided into 2-mm fragments. Disaggregation was done by 15 minutes of trypsinization (10 mL of fresh 0.25% trypsin–edetic acid). The enzyme tumor suspension was diluted up to 50 mL with RPMI 1640 and 10% heat-inactivated fetal calf serum plus antibiotics (complete tissue culture media), filtered through a four-layer No. 200 nylon mesh, and spun at 200 g. The pellet was washed once in complete tissue culture medium and resuspended to a final concentration of 2×10^5 cells per milliliter. Viability of injected cells was determined by trypan blue exclusion technique ranging between 90% and 95%.

ICV Injection

Male C57BL/6Ros mice, 6 to 8 weeks old, were fasted overnight. They were anesthetized by intraperitoneal (IP) injection of pentobarbital sodium, 55 mg/kg. The cecum was exteriorized through a low midline limited laparotomy (LAP). The ICV was identified in the mesentery. With a 30-gauge needle and 1-mL tuberculin syringe, 0.3 mL of the cell suspension was injected into the vein. Gentle pressure with a cotton-tipped applicator over the injection site for one minute achieved hemostasis. The cecum was returned to the peritoneal cavity, care being taken to prevent torsion. The wound was closed in layers.

HEP

Animals were fasted overnight and reanesthetized by IP pentobarbital, 50 mg/kg. An upper abdomen midline incision was used. The liver was freed of all fibrous attachments and exteriorized. The lateral portions of the median and right lobes were dissected. A 4-0 silk tie was used for mass ligation. The lobes were resected and hemostasis was obtained. The liver was returned to the peritoneal cavity and the wound was closed in layers. The operative mortality for the hepatectomy was 4%.

Survival after ileocolic vein injection (ICV) of MCA-38. Group 1 mice received their hepatectomy or sham laparotomy seven days after ICV injection. Group 2 mice received it 14 days after injection. Group 3 received it 21 days after injection. Survival is shown as total days of survival after injection of ICV with MCA-38. There is significant difference in survival in hepatectomized mice when compared with sham-operated-on controls (χ^2, $P=.05$). In both groups 2 and 3, hepatectomized mice survived significantly longer than their sham-operated-on controls (*t* test, $P=.05$).

LAP

Animals were fasted overnight and anesthetized by IP pentobarbital sodium, 50 mg/kg. Through an upper midline incision, liver was dissected free from all fibrous attachments and eviscerated. After gentle manipulation, it was returned to the peritoneal cavity and the wound was closed in layers.

Survival

All experimental animals had their ears marked, and were inspected twice a day until their death. Date of death was recorded in all animals.

RESULTS

The 8- to 10-week-old C57BL/6Ros mice had a 0.3-mL suspension containing 2×10^5 viable liver-derived MCA-38 cells from a syngeneic donor injected into the portal circulation, using the ICV. In 99% of those injected, foci of liver metastases were obtained in all lobes with an operative mortality of 2%. Survivors (49 animals) were randomly assigned to a HEP group or LAP control group on days 7, 14, or 21 following injection. All animals were observed twice a day and followed up until their death.

Survival in the HEP group was significantly prolonged ($P=.05$) over LAP controls when HEP was performed 14 or 21 days after injection (Figure). When HEP was performed seven days after ICV injection, no difference ($P=.05$) in survival was noted (Figure).

Survival of HEP mice vs LAP mice alone was analyzed by the χ^2 method. Separate survivals on days 7, 14, and 21 following injection were analyzed by *t* test.

COMMENT

Dissemination of the tumor via the portal vein has been shown to be the route of spread to the liver[6-8] for colonic carcinoma. Multiple modalities of therapy have been tried to control the disease and improve survival. Resection of the primary tumor without treatment of the metastases yields a median survival of 4.1 to 12 months.[1] In a 1984 report, Wagner et al[9] identified the fate of hepatic metastases from colorectal carcinoma that were left unresected: 50% of the patients with solitary metastases were alive at two years, but only 20% were alive at three years. As expected, those patients with multiple metastases did considerably worse.[9]

The limited tolerance of the liver to radiation therapy curtails external beam or internal radiotherapy for curative purposes. Multiple chemotherapeutic agents and routes of administration have been investigated: partial responses, short duration of response, lack of complete responses, and high toxic reactions are the most important mitigating factors of this treatment modality.[10] The search continues for new drugs and biologic response modifiers capable of inducing complete response with acceptable toxicity.

Woodington and Waugh[11] reported that 20% of 25 patients who sustained partial HEP as therapy for liver metastases survived five or more years with an operative mortality of 4%. As more experience with this approach was gained, an improvement in five-year survival was noted.[9,12-14] Presently, five-year survival rates up to 45% have been obtained.[15]

In vivo and in vitro experimental data on the effect of partial HEP have been controversial. Craddock et al[16] reported that partial HEP triggers DNA synthesis in the liver and lymphoid organs. Ono et al[17] found activation of effector lymphocytes following partial HEP. Natural killer cells and autoreactive cytotoxic T cells were present. Ono et al[2] also demonstrated regression and disappearance of inoculated mouse ascitic hepatoma (MH-B4) after HEP.

Others have reported progression of disease following HEP.[3,4,18] A limiting factor in this area of research has been the lack of a reproducible model of liver metastases in animals with intact immune systems. The model utilizing intraportal vein injection, described by Koike et al,[19] resulted in an unacceptable mortality rate. Intrasplenic injection followed by splenectomy was also reported.[20,21] The changes in the immune system subsequent to splenectomy alone add an important variable in this model that cannot be disregarded.

Goldrosen et al[5] described an experimental model to induce liver metastases in a single-stage procedure, simulating the natural history of the disease. Using the ICV, a 98% success rate was obtained with an acceptable 6.1% mortality. They described the metastatic process in this model to be in three stages. The covert stage is from one day after injection to ten days. Micrometastases can be identified beginning on day 11. By 21 days after injection palpable and visible macrometastases are found. An average survival of 53.3 days was reported.

Utilizing this tumor-bearing model, we found partial HEP significantly prolonged survival. We investigated this beneficial effect and believe that modulation of the immune response[22] by partial HEP may account for this improved survival. This phenomenon is believed to be separate from simple tumor burden reduction.

It remains to be proved that this mechanism is present in humans after HEP for colorectal metastasis to the liver. Further studies will also address the amount of resection needed to trigger this immune response and whether formal lobectomy is necessary or the effect can be seen after metastasectomy alone.

Discussion

Q It is clearly a surgical feat to be able to do HEPs on mice and have them survive. (1) Do you get tumor implants at your injection site? (2) If in fact you do not believe that the reason for prolonged survival is decreased tumor burden, what is it due to?

A The answer to this second question is going to be our next report. Dr Abdul will explain why this phenomenon is happening, so if you stay for the next 15 minutes you are going to receive the answer. We have been looking at the injection site and there is no seeding in the mesentery. Why, we do not know, but we do not get seeding in the site of the injection.

Q Did any of the animals in the surgical group die as a result of the operation, or are you only looking at those that survived the operation?

A Yes, about 4% of our animals die during the HEP or during the first 24 hours after the HEP. When we started trying to define the 42% HEP in the model, we had a pretty high mortality, so then we went through the operating microscope and we found out that if we avoid the hepatic biliary vein, we decreased the mortality to 4%; we do not use the operating microscope now.

Q Although you say that there was no change or no reduction or no effect of the change in the tumor burden, have you actually tried to measure the tumor burden in the residual left lobe at the time of partial HEP and again at subsequent times?

A Yes indeed, we have been doing this. We do not have the data, but we considered that whatever is happening is related to changes in the immune system.

Q Was there any weight loss following the HEP in the animals?

A Not that we observed.

Q Two questions: When you operated on these animals, you did not totally remove all the tumors. Is that correct?

A That is correct; they had tumors in all lobes.

Q So you essentially removed what is considered to be 47%.

A Forty-two percent.

Q Forty-two percent of the tumor. There was remaining tumor so you are invoking that these animals had prolonged survival, not only from the cytoreductive surgery, but also because there is something else in play. So now the magic question is what else? This is an interesting model. What are you going to do to study what comes into play or what do you think comes into play from this point?

A We have been interested in what is going on in the nonhepatic liver cells in response to the HEP. At the University of Yokahama (Japan), they showed that when you do HEPs, you have increased natural killer cell activity.

Q I think this is very important because over the last five years we have become much more aggressive with hepatic mestastases and the point is, are we doing more than just cytoreductive surgery or ridding the liver of metastases, or is something else in play? It is possible that there is something else in play and I think that this model may help to delineate that something. I like this approach.

ARCHIVES OF INTERNAL MEDICINE

Clinical Symptoms and Length of Survival in Patients With Terminal Cancer

David B. Reuben, MD; Vincent Mor, PhD; Jeff Hiris

Planning terminal care for patients with malignant neoplasms is difficult, in part, because accurate measures of prognosis have not been defined. Using data from the National Hospice Study, we examined the correlation of 14 easily assessable clinical symptoms with survival in patients with terminal cancer. Performance status was the most important clinical factor in estimating survival time, but five other symptoms had independent predictive value as well (shortness of breath, problems eating or anorexia, trouble swallowing, dry mouth, and weight loss). We generated four parametric accelerated time survival models to estimate survival in patients with combinations of these symptoms and validated the log-normal model on the entire data set. This model was unaffected by patient age, sex, primary tumor type, or site. Our findings illustrate the value of biologically "soft" clinical data in predicting survival in patients with terminal cancer. The prevalence of similar symptoms among patients with cancer of various primary and metastatic sites also supports the concept of a common final clinical pathway in patients with advanced malignant neoplasms (*Arch Intern Med* 1988;148:1586-1591).

Partial Hepatectomy Augments the Liver's Antitumor Response

Ralph Doerr, MD; Manuel Castillo, MD; Paul Evans, MS;
Norman Paolini, MS; Martin Goldrosen, PhD; Stephan A. Cohen, PhD

• Despite adequate locoregional control, colorectal metastasis to the liver remains a significant cause of death. Resection of hepatic metastasis improves five-year survival 18% to 34%. A study of the impact of 40% partial hepatectomy on cytokine production in the liver was undertaken. Nonparenchymal liver cells (NPCs) were prepared by collagenase perfusion and metrizamide gradient from partially hepatectomized and laparotomized control C57BL/6Ros mice. Nonparenchymal cell from partially hepatectomized mice compared with laparotomized mice showed a twofold to threefold increase in interferon (IFN) activity. Both interferon alpha/beta and supernatants from cultured NPCs of partially hepatectomized mice suppressed the proliferation of liver-derived MCA-38 colon adenocarcinoma cells in vitro. This tumor has been shown to metastasize to the liver of C57BL/6Ros mice. The production of various cytokines by NPCs induced by partial hepatectomy may provide a possible antimetastatic mechanism.

(*Arch Surg* 1989;124:170-174)

Sinusoidal or nonparenchymal liver cells (NPCs) play an important protective role in clearing potentially pathogenic substances such as viruses, bacteria, and endotoxin.[1] Recent reports[2-6] have demonstrated that these same cells may have the potential to eliminate metastatic tumors that arise from the colon. Both cell-cell contact and the production of cytotoxic or cytostatic factors are suggestive mechanisms. Colon-derived tumors in humans have been shown to metastasize to the liver at a high rate.[7] Recently, this laboratory developed a model system in mice that simulates the hepatic metastasis of human colon carcinoma.[8] The resection of metastatic colorectal cancer of the liver has been shown to prolong survival in some patients.[9-13] Our study is designed to determine whether this therapeutic effect is due to reduction of the tumor burden or the result of the surgery on the liver's antitumor system.

Evidence is presented herein that partial hepatectomy can augment the liver's host defense system by enhancing cytostatic or cytotoxic antitumor activity of NPCs.

MATERIALS AND METHODS

Animals

Adult 8- to 10-week-old male C57BL/6Ros mice received a standard mouse diet of pellets and water ad libitum.

Medium

Tissue culture medium consisted of RPMI 1640 medium supplemented with 25 mmol/L of HEPES, gentamicin (50 μg/mL), and 10% fetal bovine serum.

Reagents

Collagenase type IV, bovine serum albumin, and murine interferon (IFN) alpha/beta were used in the study.

Preparation of NPCs

Nonparenchymal liver cells were isolated by modifying a previously described method.[3,14] Briefly, mice were killed by cervical dislocation, the skin over the abdomen and chest was reflected, and the inferior vena cava was ligated above the diaphragm. The inferior vena cava below the liver was cannulated with a heparinized 20-gauge needle. The liver was preperfused at 37°C with 40 mL of Hank's balanced salt solution (HBSS) without Ca^{++} and Mg^{++} (pH 7.2) delivered over two minutes with the outflow through an incision in the portal vein. The liver was then perfused with 100 mL of sterile HBSS (pH 7.6) and supplemented with 0.05% type IV collagenase delivered over five minutes. The distended and blanched liver was removed, rinsed with HBSS, teased apart with a rubber policeman, and passed through a 100-μm nylon mesh screen.

Five milliliters of a single liver cell suspension was mixed with 7 mL of 30% wt/vol metrizamide dissolved in HBSS (without sodium chloride), then gently overlaid with 1 mL of HBSS (with sodium chloride) and centrifuged at 550 g for 15 minutes at 23°C. The NPCs were collected from the interface, washed twice in HBSS, and resuspended in tissue culture medium. The NPCs obtained were greater than 95% viable by this method.

Assay of Cytotoxic Activity

The target cells were adapted to continuous growth in tissue culture medium and labeled with sodium chromate ($^{51}Na_2CrO_4$) for one hour at 37°C (100 mCi/10^6 cells). The chromium phosphate Cr 51–release assay was performed in 96-well, flat-bottomed tissue culture plates. The NPCs were mixed with 2×10^4 tumor target cells in triplicate in a total volume of 100 μL and incubated for 18 hours in a humidified atmosphere of 5% carbon dioxide in air. Supernatants were harvested and counted in a gamma counter. The results were expressed as the percentage of specific release calculated by using the following equation: % specific release = $100 \times (AB/CB)$, where A indicates counts per minute from experimental cells; B, counts per minute from spontaneous release; and C, counts per minute from target cells. YAC-1 target cells were used in this study and were free of mycoplasma.

Assay of Murine IFN Activity

Interferon samples were prepared by incubation of cells in 96-well, flat-bottomed tissue culture plates. Interferon in cell-free supernatants was measured by inhibition of the cytopathic effect of vesicular stomatitis virus against a mouse fibroblast L cell line (L929) using the method of Finter.[15] Briefly, L cells were seeded into 24-well tissue culture plates (6×10^4 cells per well) and allowed to form confluent monolayers. The cells were then overlayed with serial dilutions of the test supernatant or reference IFN and incubated overnight at 37°C. After removal of the IFN, the cells were challenged with vesicular stomatitis virus (≈40 plaque-forming units per well). After 24 hours, the cells were stained with a 1% solution of crystal violet, and the percentage of lysis was determined. One unit of IFN was defined as the highest dilution causing a 50% reduction in cytopathic effect and is reported in National Institutes of Health reference units per milliliter. The lower limit of detection in this assay was 20 U/mL.

Rabbit antimouse IFN alpha/beta was used in the study. A 1:140 dilution of anti-IFN neutralized 100 U of IFN alpha/beta.[16]

Preparation of Liver-Derived (LD) MCA-38 Tumor Cells

Mice bearing liver tumors between the sixth and eighth week after ileocolic vein injection were killed and pinned to a dissecting board. The liver was exteriorized by a midline incision. A lobe-by-lobe hepatectomy was performed into a glass Petri dish containing 10 mL of 0.25% trypsin–edetic acid maintained at 4°C.

Tumor nodules were carefully dissected from normal liver tissue, and nonnecrotic tissue and nonnecrotic portions were cut into 2- to 3-mm fragments using a scalpel blade and fine forceps. These fragments were collected into a 50-mL plastic tube containing 10 mL of fresh 0.25 trypsin–edetic acid and rotated for 15 minutes. The resulting tumor enzyme suspension was diluted up to 50 mL using RPMI 1640 medium with 10% fetal bovine serum plus gentamicin, filtered through a four-layer No. 200 nylon mesh, and spun at 200 g. This pellet was washed once in medium and resuspended to a final concentration of 2×10^4 cells/mL. Viability of cells was determined by trypan blue dye exclusion and usually was greater than 90%.

Laparotomy

Experimental mice were fasted overnight and anesthetized by intraperitoneal injection of pentobarbital sodium (60 mg/kg). A 3-cm midline incision was made from the tip of the sternum to the pubis. All lobes of the liver were carefully examined anteriorly and posteriorly using a small stainless steel retractor and saline-moistened cotton-tipped applicator. The abdomen was closed using a 5-0 nylon monofilament suture and stainless steel clips.

Hepatectomy

Experimental mice were fasted overnight and anesthetized with intraperitoneal pentobarbital sodium (60 mg/kg). An upper abdominal incision was made. The liver was freed of all fibrous attachments and eviscerated. The right lobe and lateral portion of the median lobe were dissected, avoiding injury to the gallbladder, extrahepatic biliary tree, or major vessels. A 4-0 silk tie was used for mass ligation; the lobes were resected, constituting a 42% hepatectomy by weight. Hemostasis was obtained. The liver was returned to the peritoneal cavity, and the wound was closed in layers.

Survival

All experimental animals were palpated beginning at the fourth week until death to assess hepatic tumor growth. The day of death was recorded.

RESULTS

Augmentation of Anti–YAC-1 and IFN Activity of NPCs After Hepatectomy

The NPCs from laparotomized mice were assayed for their ability to display natural cytotoxicity against the standard natural killer target, YAC-1 tumor cells. The NPCs either directly or after culture displayed little cytotoxicity (Table 1). In contrast, NPCs from mice hepatectomized seven days previously had significant natural cytotoxicity. As also shown in Table 1, IFN was detected in the culture supernatant of NPCs from hepatectomized mice.

Augmentation of Cytostatic Antitumor Activity of NPCs After Hepatectomy

Inhibition of tumor growth or cytostasis is another method to measure effector cell function. The results in Table 2 demonstrate that NPCs from hepatectomized mice were cytostatic against YAC-1 tumor cells (natural killer sensitive).[17]

Cytostatic Antitumor Activity of Culture Supernatants From NPCs After Hepatectomy

To determine if NPCs from hepatectomized mice can produce antitumor cytostatic factor(s), cells were cultured overnight and supernatants were tested for their antiproliferative activity. As in Table 3, NPCs from hepatectomized mice produced a cytostatic factor against YAC-1 tumor cells. Anti–IFN alpha/beta did not affect the cytostatic activity of these supernatants. Furthermore, IFN alpha/beta did not directly inhibit the proliferation of YAC-1 tumor cells (Figure). The NPCs contain a mixed population that includes Kupffer's cells and large granular lymphocytes or natural killer cells.[4,5,18,19] In other experiments (data not shown), the cytotoxic and cytostatic activity was confined to the lymphocyte population.

Syngeneic murine colon adenocarcinoma cells (LD-MCA-38) have been previously shown to form metastatic foci in the liver if injected into the ileocolic vein.[8] Furthermore, hepatectomy seems to increase the liver span of hepatectomized mice previously injected with LD-MCA-38 through the ileocolic vein. Therefore, experiments were carried out to determine if hepatectomy of mice could induce cytostatic antitumor factors by NPCs against this freshly excised tumor. Table 4 shows that culture supernatants from

Cytostatic effect of interferon alpha/beta on liver-derived MCA-38 and YAC-1 cell lines.

laparotomized mice have antiproliferative effects against freshly excised LD-MCA-38 tumor cells. Moreover, supernatants of NPCs from hepatectomized mice exert an even greater antiproliferative effect. Anti–IFN alpha/beta partially neutralized some of this cytostatic activity. As shown in the Figure, IFN alpha/beta can also directly inhibit the proliferation of MCA-38 tumor cells.

In this study, we observed that NPCs from hepatectomized mice can induce cytolytic and cytostatic activity against the natural killer–sensitive tumor YAC-1 cells.

Statistical Analysis

Ninety-five percent confidence intervals were calculated by parameter interval estimation and compared for experimental and control groups.

COMMENT

Despite adequate local and regional control of colorectal carcinoma, metastasis to the liver remains directly or indirectly the most frequent cause of death.[9] Numerous studies have established that resection of liver metastases from colorectal carcinoma substantially improves five-year survival from 18% to 34%.[13,20] It seems unlikely that the resected metastases are the only sites of disease in the liver.

Prior studies on the effect of hepatectomy on tumor growth in experimental animals have yielded conflicting results. Paschis et al[21] transplanted Morris hepatomas and found that the feedback mechanism for growth inhibition was disrupted by the same process that permits liver regeneration following partial hepatectomy. Increased hepatic metastases were noted in the Walker 256 carcinosarcoma system if hepatectomy was performed at the time of tumor transplantation.[22,23] This effect was lost if hepatectomy preceded tumor implantation by 48 hours. In contrast, Ono et al[24] recently observed complete regression of a transplanted mouse hepatoma (MH-134) growing under the dorsal skin in syngeneic hosts after hepatectomy.

Part of the difficulty in studying the effect of hepatectomy on metastasis has been the lack of a reproducible colon-derived hepatic metastasis model. Recently, our laboratory developed a technique for induction of murine hepatic metastases through vascular seeding. Goldrosen et al[5] injected LD-MCA-38 tumor cells into the ileocolic vein of C57BL/6 mice and obtained metastatic liver foci.

The advantage of this system is a staged progression of metastasis. Utilizing this model, we determined that partial hepatectomy imparts significant improvement in survival in the tumor-bearing host.[25] Fourteen days after injection of the tumor, the time corresponding to the establishment of micrometastases in the liver, partial hepatectomy resulted in 34% improvement in survival. Partial hepatectomy 21 days after tumor inoculation, a phase that corresponds to visible macroscopic foci, improved survival by 52.5%. The mechanism by which this therapeutic effect of partial hepatectomy remains is unclear.

The liver's antitumor immune activity has been under intense scrutiny.[24-27] It has been noted that the liver regeneration that follows partial hepatectomy is characterized by an oncofetal antigen expression capable of immunizing the host. The Kupffer cells have been postulated as the stimulators of this response.[26] These liver-derived macrophages, which constitute 30% of the total cell population of the liver and up to 50% of the total fixed macrophages in the body, undergo intense DNA synthesis during the liver regeneration phase following partial hepatectomy. Furthermore, nonspecific lymphocyte proliferation with high rates of differentiation and mitosis has also been identified following hepatectomy.[27]

Partial hepatectomy triggers DNA synthesis in other lymphoid organs besides the liver. Ono et al[24] demonstrated that following hepatectomy of syngeneic mice, natural killer activity is substantially increased in the spleen if measured five to seven days after hepatectomy. More recently, this same group[28] described augmentation of lymphokine-activated killer precursors in the spleen five to seven days after hepatectomy. Hellstrom et al[29] found lymph nodes from hepatectomized mice cytotoxic for tumor cells in culture. However, few studies on the antitumor studies have been carried out with isolated NPCs after hepatectomy.

We observed that NPCs from mice hepatectomized seven days previously can induce cytolytic activity against the natural killer–sensitive tumor YAC-1. Furthermore, these same cells can produce cytostatic factor(s) against YAC-1 as well as freshly excised colon-derived MCA-38 tumor cells. The cytostatic activity of NPCs against YAC-1 seems to be independent of IFN alpha/beta, since this cytokine has no direct cytostatic effect on this tumor (Figure). However, the antiproliferative effect against LD-MCA-38 may be partly due to the direct effect of IFN on these cells, since some IFN was detected in the culture supernatants of NPCs from hepatectomized mice (data not shown). In addition, IFN alpha/beta can directly inhibit the proliferation of MCA-38 cells at concentrations produced by the NPCs (Figure).

Since Kupffer's cells (AdNPC) from hepatectomized mice did not exert any antitumor activity, it seems that the cell population from C57BL/6 mice responsible for cytolysis and cytostasis against YAC-1 is the natural killer. We have previously shown that natural killer/large granular lymphocytes in the liver from normal C3HeB/FeJ mice and Wistar rats can exert cytotoxicity against YAC-1 cells. However, NPCs from C57BL/6 mice have little cytotoxicity and little detectable IFN.[2,30] It seems that hepatectomy may induce the production of IFN that augments in situ natural killer activity.

Partial hepatectomy performed at the time of resection for colorectal metastases exerts a profound immune effect both on remaining liver tissue and possible occult metastasis. Further studies should be carried out to understand better the biology of hepatectomy to take advantage of this procedure in the treatment of colorectal liver metastasis.

Discussion

Q This is a stimulating paper for me. You could not have picked a better mouse system. The C57 black mouse has a super immune system. If you would have used the DBA or the C3H mouse, you might have found a different result. But this particular immune system is super, and when you begin to look at some of the immune stimulatory mechanisms that you saw, this reflects on some information that was discovered a number of years ago when we started to look at antithymocyte serum and antilymphocyte serum in this particular strain of mouse and then induced polyoma tumors. We found that C57 black mice had tremendous resistance against those tumors when compared with the C3H or the DBA mice, so strain selection may have worked in your favor.

A I think that's one thing of interest, but I do not think that it makes a tremendous difference what the size of the resection is. Whether it's large or small, you are going to get that immune response.

Q I am quite surprised by these results. When I was at the National Cancer Institute, Bethesda, Md, we looked at an intraperitoneal tumor model where we performed a laparotomy three days, 14 days, or five weeks after tumor inoculation, and we would see tremendous promotion of tumor growth intraperitoneally, especially at the laparotomy site, that could not be overcome with interleukin 2 lymphokine-activated killer treatment. So, in the discussion of these results, we hinted that growth factors such as B-cell growth factor and cell growth factor (TGF) beta might be one of the reasons why we saw this tremendous growth promotion of tumor. The TGF beta, being an interleukin 2 inhibitor or neutralizer, would offer an explanation for the tumor promotion we saw, which would wear off by 14 days.

I noted that in the seven-day model herein, you did not see a favorable outcome by day 14, and by day 21 you did. Are you monitoring growth factors that should be present after hemihepatectomy and that are responsible for liver regeneration?

A We are looking at TGF beta at this point. We have the probes for that. Interestingly enough, we have antiproliferative activity in the supernatants from the MCA-38s so that so far it's had an inhibitory effect, which I know is paradoxical. I really do not have an explanation at this point. We're not doing anything with the prostaglandins.

Q I looked at a rat model back in the late 1960s. When you do a partial hepatectomy, it's the best-known model for synchronization of protein synthesis, DNA synthesis, and everything, so it makes it much easier to study different pathways. I think you are just activating multiple different pathways by doing a partial hepatectomy. The other thing that I think is probably important is the activation of the complement cascade.

A Unfortunately, the rat is a much better model for the ileocolic vein injection, but we have not been able to get the tumors to grow in the liver.

Q I am disturbed by one major thing: there does not seem to be a dose response to this. In other words, you said it does not matter how much liver you remove. Did you really study that carefully? Did you find out if removing half the liver produces more of a cytokine response than taking out a little?

A No, we have not done that. All we have done is removed 42% of the liver.

Q If this is really a biologic phenomenon, there should be some sort of dose response.

Q You comment that on these patients you are asking for interleukin 1, and I presume you are doing a routine laboratory cytokine proliferation assay. Have you thought to look for hepatocyte stimulatory factors, recently described as interleukin 6, that cross-react in that assay and probably is the active agent in promonocytes? I wonder if you have had a chance to check for that. That might be contaminating your assessment of the interleukin 1 levels after hepatectomy.

A I think the interleukin 6 is something that we have been calling leukoregalin. Yes, we are looking at it, but to date, we do not have the data.

ARCHIVES OF INTERNAL MEDICINE

National Study of Internal Medicine Manpower: XII. The Future of Graduate Medical Education in Internal Medicine: What Do Program Directors Predict?

Lu Ann Aday, PhD; Ronald M. Andersen, PhD; Gerald S. Levey, MD; Christopher S. Lyttle, MA; Llewellyn J. Cornelius, MA; Catherine F. Glen

The 1985-1986 National Study of Internal Medicine Manpower asked directors of residency and fellowship programs about their plans to change the size of their programs in the near future. The vast majority (71% to 76%) of the directors expected their programs to remain about the same size for the next couple of years. For fellowship directors, this reflects a decline in the number planning to increase their program size since 1976-1977 from 32% to 18%. Directors of programs that are principal affiliates of medical schools are more likely to plan a decrease, while Veterans Administration directors are more likely to plan an increase in program size. The reason residency directors cited most frequently as important to their plans to increase program size was a perceived shortage of internists. Fellowship directors most frequently cited the need for fellows in clinical research. Stipend availability was the most important factor that influenced plans to decrease program size. Overall, residency and fellowship directors planned to increase the size of their programs around 1%. Program directors and others in the internal medicine community should consider how they can change the stipend availability, admissions criteria, and other incentives to channel trainees into the areas of greatest potential need and demand for the profession (*Arch Intern Med* 1988;148:1509-1514).

Prolongation of Survival of Nude Mice Bearing Human Colon Cancer

Treatment With Yttrium 90–Labeled Anti–Carcinoembryonic Antigen Antibody

David M. Hyams, MD; Jose M. Esteban, MD; Barbara G. Beatty, PhD; Philip M. Wanek, RPh; J. David Beatty, MD

• Nude mice bearing diffuse intraperitoneal carcinomatosis of the human colon cancer cell line LS174T were treated with an anti–carcinoembryonic antigen monoclonal antibody (MAB) that was labeled with yttrium 90 (^{90}Y-ZCE025). Control animals were either untreated or treated with nonspecific ^{90}Y-MAB (^{90}Y-96.5c). The median survival (MS) for untreated animals was 26 days. The MS for specific and nonspecific therapy that consisted of 120 μCi of ^{90}Y-MAB was 69 and 34 days, respectively. No significant improvement in the MS was observed with a second 120-μCi administration of ^{90}Y-MAB given two weeks later. A decreased MS was observed with 80 μCi of ^{90}Y-MAB given every four days for three cycles. In each category, specific therapy had a significant advantage over nonspecific therapy in increased effectiveness and decreased toxicity. The ^{90}Y-ZCE025 therapy gave an increased life span of almost 200%. The therapeutic effects with different dosing regimens have important implications for treatment planning.

(*Arch Surg* 1989;124:175-179)

The curative treatment of colorectal adenocarcinoma consists of surgical resection and radiation therapy. However, both of these modalities are limited by the anatomic location of the disease, as well as its degree of dissemination. At the present time, systemic chemotherapy offers no curative hope for afflicted patients.

Monoclonal antibodies (MABs) have the potential to improve on nonsurgical therapies by enabling tumor-directed delivery of high-dose pharmacologic or radiation therapy. Such tumor "targeting" could increase the therapeutic index by providing more toxic therapy to malignant cells, while minimally affecting normal tissues.[1,2]

In a previous publication, we described a nude mouse model for human colon carcinomatosis, successfully treated with yttrium 90–labeled anti–carcinoembryonic antigen (CEA) antibody.[3] Doses of the potent beta emitter ^{90}Y ranged from 40 to 160 μCi. Treated animals that were killed 12 days after therapy had consistently lower tumor burdens than untreated animals, or than animals that were undergoing treatment with a ^{90}Y-labeled nonspecific MAB.

The present study was designed to elaborate on these findings by determining whether such therapy might offer a significant survival advantage. In addition, the search for an optimal dosing scheme for the administration of ^{90}Y-labeled anti–CEA antibody in a CEA-producing tumor-bearing animal has been commenced.

MATERIALS AND METHODS

Tumor Cell Line

The LS174T cells, derived from a CEA-producing human colon cancer, were maintained in a monolayer culture in low-glucose Dulbecco's modified Eagle's medium and HAM's F-12 (1:1) containing 7.5% fetal calf serum, 1% glutamine, 1.5% HEPES buffer, and 100 000 U of penicillin-streptomycin (Irvine Scientific, Santa Ana, Calif). To prevent culture-induced phenotypic drift, cell cultures were restarted from frozen stock every three months. Using this technique, CEA production by the LS174T cell line, as measured by enzyme immunoassay (Roche Diagnostics, Nutley, NJ), was stable. Before inoculation, cells were washed with phosphate-buffered saline solution (PBSS)–0.1 mmol/L of edetic acid (EDTA), trypsinized with 0.25% trypsin, washed once in complete media, and resuspended to the appropriate concentration in PBSS.

Animal Model

Six-week-old female nu/nu BALB/c mice, weighing 20 to 25 g (University of California, San Diego), were maintained in a closed colony, as previously described.[4] Animals received an intraperitoneal (IP) injection of 0.2 mL of rabbit anti–mouse lymphocyte

*Control animals received no treatment; nonspecific treatment was with ^{90}Y-labeled 96.5c monoclonal antibody; and specific treatment was with ^{90}Y-labeled ZCE025 monoclonal antibody.

serum (cytotoxic titer, 1:6400; M. A. Bioproducts, Walkersville, Md). Simultaneously, 8×10^5 cells of LS174T were injected IP in 1 mL of PBSS. As described previously, random autopsy seven days after inoculation consistently demonstrated multiple macroscopic tumor nodules of 0.2 to 2 mm that lined that peritoneal surface.

Antibodies

The term ZCE025 refers to a murine IgG1 MAB directed to an epitope of CEA. The MAB, 96.5c, is a murine IgG2a with specificity for the p97 antigen of melanoma (Hybritech Inc, San Diego). Purification of ZCE025 and 96.5c, and labeling with ^{90}Y was accomplished through a modified proprietary diethylenetriamine pentaacetic acid technique.[3]

Each antibody dose was calibrated by making a 1:100 dilution of stock, radiolabeled MAB and counting 10 μL in 5 mL of aqueous counting scintillant. The ^{32}P channel of a liquid scintillation counter (Beckman LS150, Beckman Instruments, Fullerton, Calif) was used for each measurement. This channel was calibrated to a standard traceable to the National Bureau of Standards. Appropriate dilutions of the stock solution was made in PBSS. All of the antibody was used within 72 hours of preparation and diluted immediately before injection.

Therapeutic Regimen

Seven days after tumor inoculation, animals for each experiment were randomized into three groups that received either no therapy, therapy with nonspecific ^{90}Y-labeled MAB (96.5c), or therapy with ^{90}Y-labeled specific anti–CEA MAB (ZCE025). A 1-mL injection of radiolabeled MAB in PBSS was given IP to the animals in the treatment groups. Three different ^{90}Y-MAB treatment regimens were studied: one cycle of 120 μCi given on day 7, two cycles of 120 μCi given on days 7 and 21, and three cycles of 80 μCi given on days 7, 11, and 15. Radiolabeled MAB was administered with a specific activity of 30 μCi/μg. In the dose range used, unlabeled MAB had previously been shown to be nontherapeutic.

Animals were maintained four to a cage with ad libitum food and water. Deaths were recorded as they occurred, noting whether the death was due to treatment toxicity (treatment death) or malignant disease progression (disease death). Survival (treatment and disease deaths combined) was plotted using the Kaplan-Meier technique, while statistical analysis was accomplished using the generalized Wilcoxon method.

RESULTS

The animal model utilized was chosen for its reliability and reproducibility. Seven days after inoculation, animals undergoing random autopsy had multiple tumor nodules of 0.2 to 2.0 mm over the peritoneal surface. Each of these nodules consistently demonstrated the characteristic histologic pattern of a human adenocarcinoma, with exuberant CEA production as shown by immunohistochemical studies. Vascular ingrowth consistent with established tumor was readily seen. Furthermore, the pattern of spread mimicked the transperitoneal carcinomatosis of human colorectal tumor growth. As in humans, tumor growth resulted in the death of the animals.

A total of 39 animals served as concurrent no treatment controls. Mean survival ± SEM for these animals was 25.9 ± 1.0 days. Untreated tumor growth consistently resulted in ascites by days 16 to 18, bulky tumor by day 22, and death with hemorrhagic ascites by days 24 to 27. Tumor burdens appeared to be consistent with those seen in earlier studies (4 to 5 g). An examination of the tight clustering of the 25th, 50th, and 75th percentile "days of survival" demonstrates the consistency of the model (Table).

Our previous report demonstrated the greatest inhibition of tumor growth with doses of 120 and 160 μCi. However, 160 μCi of ^{90}Y-ZCE025 (specific treatment) also produced extensive depletion of bone marrow and treatment-associated death. Therefore, in the first series of these survival experiments, we examined the effect of 120 μCi of ^{90}Y-labeled MAB given as a single dose. There was a significant ($P<.001$) prolongation of the mean survival to 35.1 ± 7.9 days with nonspecific therapy. With the specific anti–CEA radioconjugate, a much longer mean survival of 74.8 ± 6.7 days was documented ($P<.001$). Kaplan-Meier plots demonstrating this effect on Fig 1 show an increased life span of 165%. Postmortem examination of animals allowed identification of the cause of death, whether due to disease or treatment. Animals with empty bone marrows, depleted spleens, and minimal tumor were classified as treatment deaths. Animals with extensive tumor growth were considered to be disease deaths, irrespective of the hematologic status. Treatment death was significant (3/8, 37.5%) in the animals that received 120 μCi of ^{90}Y-labeled nonspecific MAB (96.5c). No toxic deaths were noted in the animals treated with the specific MAB (ZCE025) that was labeled with 120 μCi of ^{90}Y.

Pilot investigations of a single 120-μCi dose of MAB demonstrated that the bone marrow depletion was greatest during the first week after injection of the radionuclide. Recovery was 80% of control appearance by 14 to 21 days. Therefore, we felt that a second dose of equal activity, aimed at eliminating any residual tumor, might be tolerated satisfactorily 14 days after the initial therapeutic dose. With the 120-μCi two-cycle regimen (total dose, 240 μCi), the survival advantage of nonspecific (mean ± SEM = 37.1 ± 6.4 days) over no treatment, and specific (mean ± SEM = 72.7 ± 7.0 days) over nonspecific treatment were again significant ($P<.001$) (Fig 2). Although the specific treatment group had an increased life span of 192%, the survival advantage for the two-cycle regimen compared with the single-dose regimen was not significant.

Fig 1.—Comparison of specific treatment (open triangles, 120 μCi for one dose) with identical dose regimen of nonspecific treatment (closed circles) and untreated control animals (open circles).

Fig 2.—Comparison of specific treatment (open triangles, 120 μCi every two weeks for two doses) with identical dose regimen of nonspecific treatment (closed circles) and untreated control animals (open circles).

Fig 3.—Comparison of specific treatment (open triangles, 80 μCi every four days for three doses) with identical dose regimen of nonspecific treatment (closed circles) and untreated control animals (open circles).

Fig 4.—Comparison of all specific treatment regimens (closed triangles, 120 μCi for one dose; open triangles, 120 μCi every two weeks for two doses; closed circles, 80 μCi every four days for three doses) with untreated control animals (open circles).

Toxicity (treatment death) was marginally increased to 33.3% (4/12) for animals that received nonspecific MAB therapy (96.5c) and 8.3% (1/12) for animals that received specific MAB therapy (ZCE025) by the 120-μCi two-cycle regimen (Table).

The final experiments examined more frequent administration of lower doses of ^{90}Y-MAB. This regimen was designed to accomplish a higher dose of ^{90}Y-MAB over a shorter period of time without increase of toxicity. The schedule consisted of 80 μCi of ^{90}Y-labeled MAB administered every four days for three cycles (days 7, 11, and 15), to a total activity of 240 μCi. This three-cycle regimen resulted in a marked increase in toxicity without the survival benefit of the previous regimens. Toxicity accounted for 100% (8/8) of the deaths among animals that received nonspecific ^{90}Y-MAB (96.5c) treatment (Table). Indeed, survival among untreated controls (mean ± SEM = 25.9 ± 1.0 days) was significantly better ($P<.001$) than survival of animals that received nonspecific MAB (mean ± SEM = 22.3 ± 0.7 days) (Fig 3). Toxicity accounted for 37.5% (3/8) of the deaths among animals that received specific ^{90}Y-MAB (ZCE025) treatment. While survival of all animals that received specific radioimmunotherapy (mean ± SEM = 40 ± 4.5 days) was significantly better ($P<.001$) than that of untreated tumor-bearing animals (increased life span, 65%), it was significantly poorer ($P<.001$) than that of animals that received specific therapy in either of the two preceding regimens (Fig 4).

It should be noted that all animals in this study that did not die as a result of treatment toxicity did eventually die of disease progression. No animal was "cured" of disease.

COMMENT

Since the time of their development, MABS have been proposed as antitumor agents by a number of authors.[5-7] They have since been tested in animals and humans, with a variety of conjugates designed to identify or treat malignant tumors.[8-10] While the clinical utility of MABs for radiolocalization already shows promise,[11] their greatest potential is for clinical cancer treatment.[12] A variety of studies have demonstrated a specific antineoplastic effect

of tumor-directed radiolabeled MABs.[13,14] In most of these studies, antitumor therapy has been evaluated in animals bearing subcutaneous tumors, and the end point has been suppression of tumor size. However, the critical end point in evaluating any new antineoplastic therapy is the extension of survival of the tumor-bearing host.

The IP carcinomatosis model that was previously reported by our group[3] mimics a well-recognized form of human metastatic colorectal tumor growth that routinely leads to death. Using this model, we demonstrated a significant inhibition of tumor growth by specific ^{90}Y-MAB therapy. Those studies indicated that 120 μCi of the specific radiolabeled MAB (ZCE025) produced the greatest effectiveness-toxicity ratio. The major toxicity noted was hematologic cellular depletion of bone marrow and the spleen. In the current experiment, this dose (120 μCi) translated into a dramatically increased survival advantage (increased life span, 165%). In most human colon cancer xenograft experiments, an increased life span of 30% for systemic chemotherapy is considered to be very good.

Multiple-dosing schemes were investigated to determine whether residual tumor could be eradicated and survival could be further enhanced. In the 120-μCi two-cycle experiment, intervals were chosen that would allow significant bone marrow recovery. In the 80-μCi three-cycle experiment, doses were lowered to decrease toxicity. This allowed intervals to be shortened and the number of cycles to be increased. In either case, twice the single therapeutic dose was achieved (240 μCi).

As predicted, a two-week interval prevented any significant increase in toxicity among animals that received a second 120-μCi dose of specific MAB (treatment death, 8.3%). However, there was also no significant improvement in survival when compared with the single-dose regimen. Use of the three-cycle 80-μCi dose over an eight-day period markedly increased toxicity (treatment death, 37.5%), even though the total dose was identical (240 μCi). Thus, significant hematologic toxicity occurred in these animals with repetition of the more moderate doses.

Despite an increased total dosage, there was no therapeutic benefit from repeating the ^{90}Y treatment with the specific MAB once, or even twice. Histopathologic studies in our laboratory, stimulated by the failure of the multiple-dose regimens to increase survival, have shown that the tumor, which regrows after ^{90}Y-MAB treatment, does not express CEA.[15] This loss of CEA expression may be due to clonal selection or antigenic modulation. Further studies are in progress to understand the cause of this change of antigen expression. However, the immediate therapeutic implication of the loss of CEA in ^{90}Y-MAB–treated LS174T tumor is that higher first-treatment doses of ^{90}Y-MAB will need to be administered. Examination of higher ^{90}Y-MAB doses will necessitate hematologic support (eg, bone marrow transplantation) to counteract the hematologic toxicity.

One interesting finding, consistent in all of our studies, has been the increased toxicity seen in all animals that received nonspecific MAB therapy compared with those animals that received specific radioimmunotherapy. This could not have been due to dosing or standardization errors, as each dose was prepared, calibrated, and administered concurrently with the equivalent specific treatment dose. We have deduced that this greater hematologic toxicity with the nonspecific ^{90}Y-MAB is due to differences in biodistribution between the specific and nonspecific MAB.

Biodistribution of ^{90}Y-MAB using beta emission requires tissue homogenization and bleaching for liquid scintillation counting. We have demonstrated that ^{90}Y-MAB levels in tissues can also be measured accurately and more easily in the well gamma counter using bremsstrahlung emission, provided the volume in the tube remains constant (B.G.B., 1986). Furthermore, we have shown that the biodistribution of ^{90}Y-labeled anti–CEA MAB that we have used is very similar to the biodistribution of indium 111–labeled anti–CEA MAB (B.G.B., 1986). Published biodistribution studies from our laboratory have demonstrated an inverse correlation between the tumor uptake, expressed as percent injected dose per gram, and the tumor size when specific ^{111}In-labeled anti–CEA antibody was administered.[15] A concomitant increase in the ^{111}In-MAB blood pool component paralleled diminishing tumor size. We have also found increased and prolonged blood pool circulation of radiolabeled MAB, when target antigen is decreased or absent.[17] We thus hypothesize that the nonspecific ^{90}Y-MAB had a much higher blood pool content than the specific ^{90}Y-MAB that localized to the tumor. This increased nonspecific ^{90}Y-MAB in the blood probably accounts for the higher hematologic toxicity in these animals.

Dosimetry studies will be needed before the transition from animal to human radioimmunotherapy can be made. At the present time, to our knowledge, there is no established method for measurement of tissue or organ doses of ^{90}Y. Estimations can be achieved by extrapolation of from ^{111}In-MAB gamma camera scintigraphy.[18] Studies are now in progress to compare these estimations with implantable microdosimeters and with histologic analysis in animals.

In these animal studies, we have demonstrated that anti–CEA antibodies, labeled with ^{90}Y, can kill human colon cancer cells and that they can dramatically extend survival. With continued careful studies of labeled antibody dosing, biodistribution, and tissue interaction, this modality has the potential to be an effective contributor in the management of patients with colon cancer.

This study was supported in part by a grant from the Margaret Early Foundation, Los Angeles; by Health Training Grant CA 09477, Cancer Center Core Grant CA 33572, and Program Project Grant CA 43904 from the National Institutes of Health, Bethesda, Md; and by a grant from Hybritech Inc, San Diego.

The authors wish to thank Robert Hill, PhD, Department of Biostatistics, City of Hope National Medical Center, Duarte, Calif, for his kind assistance and statistical review.

Discussion

Q The first question that I was going to ask is about the yttrium itself. What is the distance of effective radiation? Is it a very short distance?

A Yttrium is a high-energy beta emitter that emits approximately 80% of its radiation over a 3-mm distance. However, for 100% of the beta radiation, you have to go out to almost 1 cm, which is a difficult problem in a small mouse model. As you increase the dose of yttrium that you want to use for tumor control, you increase the toxicity to other areas of the animal.

Q That would be one thing that you could modify, because you could use another radioisotope, depending on what kind of model you are going to treat. For example, I do not know how iodine 125 stacks up with ^{90}Y. I imagine it must be shorter, but I am not sure about that.

A Well, iodine 131 is probably a better alternative. One of the advantages of ^{90}Y is that its path length is excellent for human use, which is, of course, the ultimate aim of the studies. All of the animal studies of radioconjugates directed against human tumor markers are somewhat crippled by the need to use a human tumor. Right now, there are no models using large animals in which you can use human tumor xenografts.

Q The second question that I had refers to antigenic modulation; at least, this is implied by the altered immunohistology after ^{90}Y therapy. Did you get the same thing in vitro with this line? Have you tried incubating with unlabeled monoclonal antibody because it is a little surprising that you had such a distinct loss of CEA after ^{90}Y therapy?

A Actually many authors have described changes in antigen expression after therapy. We have not done the in vitro studies that you suggest, but we are interested in studies that will help to distinguish between antigenic modulation and clonal selection.

Q In exactly the same tumor model with the nude mice, using the same cell line, our experience with treating them with adoptive immunotherapy with human monocytes and gamma interferon, was that a lot of the nude mice would waste away, whereas other nude mice would develop bulky IP tumor masses. So, we would see two different patterns of mortality. I am very surprised by the nice curves that you have. They start dying in the most effective treatment group, around day 80, and they are all dead by day 100. It is very surprising that you did not see any cures. Apparently, your animal facilities must be very good, because to keep them out for 80 days under these conditions is already good. However, did you see the two different patterns of dying? I ask this because the animals that wasted away practically had no tumor at all, but they still died. So, what is the cause of dying? Did you perform autopsies on all your animals?

A Autopsies were performed whenever feasible. In this study, we did not see many animals waste away. The early deaths of animals with minimal tumor we attributed to radiation toxicity. In other studies in animals without tumor, we see the same effect with toxic doses of radiation; the animals waste away. They get thin and scrawny, and they die.

Regarding the absence of cures, we share your concern. We have tried to decrease the number of cells to get a longer living model, so that we would have more time for bone marrow recovery and could give subsequent doses, but we have found that we get less consistent tumor growth. With 800 000 cells, we have a highly consistent tumor on repetitive trials, but the rate of tumor growth is very rapid. Perhaps this explains the absence of cures.

The 'Do Not Resuscitate' Order: A Profile of Its Changing Use

Palmi V. Jonsson, MD; Michael McNamee, MD; Edward W. Campion, MD

The "do not resuscitate" (DNR) order has wide-ranging ethical, legal, and economic implications. We reviewed the course of 244 patients who died during two three-month periods, in 1982 and 1986. We found that 68% of patients who died had a DNR order written, including 94% with malignancy and half of patients with cardiovascular disease. Most orders (61%) were written within three days of death, with 64% written on medical-surgical floors and 34% in critical care units. Even among patients under the age of 60 years, 57% had a DNR order written by the time of death. Ninety-one percent of DNR orders were written by attending physicians, with accompanying explanatory note in 84%. Documentation showed only 14% of patients but 77% of families being consulted. In 1983 a new two-level DNR order system defined two levels of intensity: "all but cardiopulmonary resuscitation" and "comfort measures only." Equal numbers of patients received each order in the 1986 sample. No patient was transferred to the critical care units after a DNR order had been written. The prevalence of DNR orders written for patients dying of cardiovascular disease increased from 27% to 64% over the four years. We conclude, from study of deaths in this representative community hospital, that an explicit DNR order is now the rule rather than the exception, but decisions are made late and involve family far more than the patient (*Arch Intern Med* 1988;148:2373-2375).

Survival of Patients With Stage B2 Colon Carcinoma

The Gastrointestinal Tumor Study Group Experience

Russell Nauta, MD; Donald M. Stablein, PhD; E. Douglas Holyoke, MD

• The Gastrointestinal Tumor Study Group, a multispecialty collaborative clinical research program, executed two studies of surgically resected colon carcinoma, including patients with serosal penetration but no positive regional lymph nodes (stage B2). In the first study, 232 patients with stage B2 disease were operated on and survival was unaffected by therapy. In the stage B2 group, survival was 78% at five years, and is estimated to be 64% ten years after surgery. A second study, begun in 1979, compared survival and recurrence data on patients who underwent surgical resection and were treated postoperatively with fluorouracil and hepatic irradiation vs those who were observed. Hematologic toxicity of the regimen and accumulation of data from the first study caused the termination of randomization of patients with stage B2 disease with continued registration to observation only. One hundred twenty-four untreated patients with stage B2 carcinoma had a five-year survival rate of 77%, confirming the relatively high survival of this group of patients who are treated with surgery alone. Our patients' five-year survival of 78% corresponds favorably to the 87% survival rate anticipated in an age-, sex-, and race-matched cohort of Americans not specifically diagnosed as having cancer. Adjuvant trials, in seeking improved survival, should recognize that our review of 356 patients implies a considerably higher-than-anticipated five-year survival for the patient with stage B2 disease who undergoes surgical resection. Toxicity of the marginally effective agents currently available and the large numbers of patients necessary to demonstrate an advantage in a treatment arm suggests that patients with stage B2 disease should be excluded from many adjuvant trials of colon cancer treatments.

(*Arch Surg* 1989;124:180-182)

All staging systems for colorectal carcinoma attempt to group patients with similar prognoses based on symptomatology, metastatic behavior, or mural growth patterns.[1] Such systems quantifying the depth of wall penetration of the primary tumor and the presence or absence of nodal metastases do so to determine whether these morphologic characteristics alter prognosis.

The treatment of established metastatic disease with chemotherapy in patients with colon cancer has not been demonstrated to prolong survival and such therapies usually have substantial toxicity. To offer experimental, marginally effective modalities as adjuvant treatment one is obliged to test a population at high risk to justify the toxicity of the therapy.

PATIENTS AND METHODS

Patients

The Gastrointestinal Tumor Study Group, a collaborative research organization sponsored by the Clinical Therapy Evaluation Program of the Division of Cancer Treatment, National Cancer Institute, Bethesda, Md, in 1975 began a study to compare the effects of no postoperative therapy, chemotherapy, immunotherapy, and a combination of chemotherapy and immunotherapy in patients with surgically resected colonic cancer with either serosal penetration (stage B2) or involved regional lymph nodes (stage C). The results of this protocol, GI 6175, failed to substantiate significant treatment differences, but disclosed a 78% survival after five years in patients with stage B2 disease.[2] In 1979, protocol GI 6179 began the accrual of patients who were prospectively randomized in a phase III clinical trial designed to compare combined therapy of hepatic irradiation and fluorouracil chemotherapy with a surgery-only control arm. As in the previous study, all patients had undergone potentially curative surgery with en bloc resection and negative resection margins for stage B2 or stage C colon cancers. Patients entering the study were required to have histologic proof of a colon cancer extending either through the serosa or pericolonic fat or to have positive nodes. Patients were randomly assigned to a control arm or to a combined radiotherapy/chemotherapy arm.

Because of toxicity, several reductions in protocol therapy were required.[3] On Dec 31, 1981, a treatment-related death in this study was reported, and combined with the good survival results of the patients with stage B2 disease in the prior study, we decided to exclude any more patients with stage B2 disease from therapy.

In an effort to substantiate the survival experience of patients with stage B2 disease who were observed in the first study, an additional series of 100 patients with stage B2 disease were registered and assigned to the surgery-only arm of the study.

Methods

Survival experience from all eligible patients with stage B2 disease (surgically resected colon cancer with penetration of the serosa and negative regional lymph nodes) in protocol GI 6175 and untreated patients in protocol GI 6179 with stage B2 disease was collected and analyzed. Product-limit estimates of survival distributions were calculated and log-rank tests of equality of survival curves were performed. Expected survival was calculated annually

for cohorts with identical age, sex, and race distribution using the Cancer Survival System software developed by the End Results Section of the National Cancer Institute. Relative survival is the ratio of observed actuarial survival to the expected survival of a cohort of randomly selected subjects with identical age, sex, and race composition.

RESULTS

The Table displays the characteristics of the 356 patients analyzed in this report. Sex, the number of pathologically negative nodes reported, and the percentage of patients with contiguous organ involvement were similar in the two

studies. Age distribution in the first study resulted in fewer patients in the extreme age groups, and the difference is just statistically significant ($P = .05$). Figure 1 displays the combined survival results for the studies. Five- and ten-year survival is estimated to be 78% and 64%, respectively. Notice that a cohort of randomly selected members of the population with a similar age, sex, and race distribution would be expected to have survival percentages of 87% and 72% at five and ten years, respectively. Beyond five years, these patients appear to have survival identical to randomly selected members of the population and have an excess mortality of only 9% at five years.

The survival experiences of the two protocols are plotted in Fig 2. Note that, since the follow-up on the GI 6179 protocol is not as long, only the first five years are plotted, and the survival probabilities are plotted from 0.5 to 1 to emphasize differences. No differences are observed between these two studies, as five-year survivals are estimated to be 78% and 77% in protocols GI 6175 and GI 6179, respectively. Thus, the first study's results for patients with stage B2 disease have been replicated through this time period. We have further examined sex, number of nodes examined, and contiguous organ involvement. None was statistically significant, although a large number of negative nodes and the lack of other organs involved were both protective.

Figure 3 provides the observed and expected survival by age groupings; the survival by age values are not themselves significantly different. Note that survival in the youngest and oldest groups are similar, but that the expected survival for the youngest patients is much better. Survival performance relative to expected performance is improved with advancing age, and only in patients less than 50 years of age does the difference between observed and expected survival exceed 12% at five years. In the patients over 70 years of age, the relative survival is never significantly less than unity.

COMMENT

These studies replicate the good survival of patients with surgically resected stage B2 colon cancer in the absence of effective postsurgical adjuvant therapy. We note that this is the case despite the inclusion in protocol GI 6179 of a larger number of participating institutions and a surgical base that included academic and community centers. Long-term follow-up of 356 patients with stage B2 carcinoma in two prospective randomized studies suggests that the survival achieved with surgery alone is only approximately 10% worse at five years and is statistically similar to that of the general population thereafter. While it is recognized that treatment and control groups did not differ with respect to survival in the Gastrointestinal Tumor Study Group, it is demonstrated after a median follow-up of 8.5 years that the overall survival of patients with stage B2 cancer is 78% at five years. This survival does not appear to be extensively affected by the number of nodes examined, the sex or age of the patient, or contiguous organ invasion. In historical series, rather than among trial participants, other authors[4-9] have reported five-year survivals ranging from 52% to 85%, while the National Surgical Adjuvant Breast and Bowel Project reported a 70% five-year survival rate in a preliminary report of a cohort of patients with stage B2 disease.[10] Staging requirements for trial entry, along with modern scanning capabilities, may account for much of the improvement observed in recent studies. With the possible exception of patients presenting with stage B2 disease in the fourth decade, we conclude that, because of their excellent survival, patients with stage B2 colon carcinoma are seldom appropriate candidates for adjuvant trials of toxic therapies.

Discussion

Q What was the cause of death in the 25% of patients who died? Did most of them die of colon cancer?

A A fair percentage of these patients died of causes other than colon cancer. We examined all causes of death and included the patients in the study whether they died of colon cancer or something else.

Q What percentage of your patients now have stage B2 lesions compared with ten years ago? Is there a difference in selectivity from the preoperative workup now, as opposed to ten years ago?

A There were not substantial differences in the number of patients in the B2 category accrued to the study at either time. The only difference in GI 6179 compared with GI 6175 was that we recognized that the patients with stage B2 disease appeared to be doing well and had some treatment-related toxicity; we ultimately elected in the latter study to register all of the patients with stage B2 disease rather than randomize them to therapy or no therapy.

Q Why did your patients do so well? The control group always does better than what has been generally reported. Does the quality of the initial surgical procedure have something to do with it? Obviously, any surgeon who is interested enough to be part of a study group is going to have a special interest in the neoplasm under study, and if experience means anything, that surgeon is going to perform that particular operation better than most surgeons.

A Interesting to us were the differences between the two studies in terms of the surgeons performing the procedures. Many of the patients accrued to protocol GI 6175 were accrued through university centers. Many of the patients who were ultimately entered in protocol GI 6179 were entered after surgery in a community hospital and were referred by their medical oncologist. These patients came to protocol GI 6179 by a more diverse route than they would have in the first study. Despite that, the survival curves for patients with stage B2 disease in the two studies are virtually impossible. We looked for variables to explain why our patients did better than others have reported, but found nothing.

Q Was there increased long-term morbidity in the group that received hepatic irradiation?

A The amount of radiation delivered, which was approximately 21 Gy, did not result in extraordinary toxicity. Therapy-related deaths were not related to radiation hepatitis, but to leukopenia.

Interactions of Human Colorectal Carcinoma Cells With Basement Membranes

Analysis and Correlation With Differentiation

George W. Daneker, Jr, MD; Andrew J. Piazza; Glenn D. Steele, Jr, MD, PhD; Arthur M. Mercurio, PhD

• The abilities of colorectal carcinoma cell lines to adhere and invade through a basement membrane were examined. The four poorly differentiated cell lines studied were three to four times more adherent and spread to a greater extent following adherence to a basement membrane matrix than the three moderately well-differentiated (MWD) lines. One exception was the MWD cell line DLD-2, whose histologic features resembled a signet ring carcinoma. The ability of these cells to invade through a basement membrane model was measured. This assay showed that the poorly differentiated cell lines as well as DLD-2 were three times more invasive than the remaining MWD cell lines. These data indicate that tumor cell adherence can be correlated with invasion through basement membranes. In addition, the ability of colorectal carcinoma cells to interact with the basement membrane seems, in general, to be inversely related to the degree of cytodifferentiation.

(*Arch Surg* 1989;124:183-187)

A correlation between the histologic grade and the clinical behavior of colorectal carcinomas has long been appreciated.[1] Poorly differentiated tumors are observed to have a more advanced stage at diagnosis, an earlier progression to metastasis, and a poorer prognosis per stage than moderately well-differentiated tumors.[2,3] This correlation has recently been confirmed in a multi-institutional study by the Gastrointestinal Tumor Study Group.[4] While the relationship between tumor grade and clinical behavior has been well documented, the cellular properties related to differentiation that determine biological behavior are not well understood.

One biological property that merits close examination is the interaction of carcinoma cells with the extracellular matrix or, more specifically, the basement membrane.[5-7] The adherence of these cells to basement membrane components has been proposed to be an initiating step in the processes of tumor invasion and subsequent metastases.[8,9] Adherence may also induce or modulate cellular functions, such as synthesis and secretion of degradative enzymes, and it may promote cell motility.[10,11]

Carcinoma cells adhere to basement membranes by receptor-mediated mechanisms that involve receptor binding to the glycoprotein laminin.[5-7] In a previous study, we analyzed the ability of human colorectal carcinoma cell lines to interact with this basement membrane component.[12] The results of this study demonstrated that the interaction of colorectal carcinoma cells with laminin varied according to the degree of cytodifferentiation. Poorly differentiated cell lines were able to adhere and spread on laminin to a substantially greater extent than moderately well-differentiated lines. Both adherence and spreading were shown to be mediated by a peptide sequence in the laminin molecule that is recognized by a specific cell surface receptor.[13]

In our study, we expanded the scope of our observations from cellular interactions with purified basement membrane components to interactions with an intact basement membrane. A murine sarcoma basement membrane preparation, matrigel, was used in these experiments as a basement membrane model.[14] Matrigel contains all the components of intact basement membranes, and it is able to form a solid basement membrane matrix in vitro. Initially, the ability of established colorectal carcinoma cell lines to adhere and spread on matrigel was determined. We then measured the ability of these cells to adhere, penetrate, and then migrate through a matrigel barrier in response to a soluble attractant. Finally, these data were compared with data from an assay measuring cell migration in response to soluble attractants in the absence of matrigel.

MATERIALS AND METHODS

Cell Lines

Human colorectal carcinoma cell lines that were initiated from tumor tissue and are now established in serial subculture were used. CCL 222, CCL 228, CCL 235, CCL 238,[15] Clone A, and DLD-2 were used.[16,17] CX-1 was isolated from the cell line HT-29 at the National Institutes of Health, Bethesda, Md. MIP 101 was also used.[18] Cells were routinely maintained in 45% RPMI 1640 and 45% Dulbecco's modification of Eagle's essential medium (DMEM) supplemented with 10% fetal bovine serum (FBS), 1% L-glutamine, streptomycin sulfate (50 μg/mL), and penicillin G potassium (50 U/mL). Confluent cultures were subcultured by detachment with 0.1% trypsin–0.5 mmol/L of edetic acid in phosphate-buffered saline (PBS) for five minutes at 37°C. This suspension was replated at a density that yielded single cells in a logarithmic growth phase for their use in the assays described below. The cell lines were subcultured at least 24 to 48 hours before these assays were performed. Cells were routinely screened for mycoplasmal DNA by staining with Hoescht stain 33258 and were determined to be free of mycoplasmal contamination on this basis.

Preparation of Matrigel

The basement membrane extract matrigel was prepared from Englebreth-Holm-Swarm sarcoma.[14] The sarcoma was grown as allografts in C57/BL16 mice. After harvesting, the tumor tissue was washed in 3.4 mol/L of sodium chloride and 0.05 mol/L of Tris hydrochloride (HCl), pH 7.4, containing protease inhibitors. The tissue was extracted with 2.0 mol/L of urea and 0.05 mol/L of Tris HCl, pH 7.4 (1 mL per gram of tissue), at 4°C overnight. This mixture was then centrifuged at 10 000 g for 30 minutes at 4°C. The extract was collected, and the pellet was washed once with an equal volume of the urea buffer. The extract and the wash were then combined and dialyzed against 0.05 mol/L of Tris HCl, pH 7.4, containing 0.15 mol/L of sodium chloride at 4°C overnight. The dialyzed extract was centrifuged at 15 000 rpm for 20 minutes at 4°C, and the supernatant (matrigel) was stored at −20°C.

Adherence Assays

Multiwell (11.3-mm) tissue culture plates were coated with either matrigel or bovine serum albumin (BSA) by incubation with a 20-μg/mL solution of these proteins in PBS at 4°C overnight. The wells were then washed twice with Hank's balanced salt solution (HBSS) and incubated with serum-free DMEM at 37°C for 30 minutes before their use in the assays.

For the assays, a cell suspension (see above) was added to DMEM containing 10% FBS to inactivate the trypsin and centrifuged at 1000 rpm for five minutes. The cell pellet was resuspended in DMEM containing 1.0% BSA. Cells were counted visually using a hemocytometer. Viability was assessed by trypan blue dye exclusion and only suspensions with more than 95% viability were used. An aliquot (200 μL) of the cell suspension containing 5×10^5 cells per milliliter was added to the protein-coated wells. The plates were incubated at 37°C in a humidified atmosphere of 95% air and 5% carbon dioxide (CO_2) for 75 minutes. The nonadherent cells were then removed by two gentle washes with warm HBSS. Adherent cells were fixed with methanol and stained with a 10% (vol/vol) solution of Giemsa stain in PBS. These cells were viewed using brightfield optics with a microscope (Nikon Diaphot) equipped with a 16-square reticle. With a 20× objective, the surface area of this grid was 0.25 mm². For each adhesion assay, the number of cells in the reticle was determined in triplicate. Results for these experiments are expressed as the mean number of adherent cells per reticle. The extent of cell spreading was also evaluated in these assays. Spreading was defined as an extension of cytoplasmic processes resulting in a deviation from the rounded morphologic features seen immediately after the addition of the cells to the tissue culture plates.

Adherence assays performed in the presence of the protein synthesis inhibitor cycloheximide were carried out in a similar manner. Cycloheximide was added immediately after resuspension of cells in DMEM containing 1.0% BSA. The final concentration of cycloheximide in the cell suspension was 75 μg/mL.

Cells destined for use in delayed plating assays were incubated for one hour at 37°C in a humidified atmosphere of 95% air and 5% CO_2 after resuspension in DMEM containing 1.0% BSA. After this incubation period, the cell suspension was added to wells containing matrigel or BSA.

Assays of Migration in Response to a Soluble Attractant (Chemotaxis)

Assays for chemotaxis and chemoinvasion were performed in a modified microchamber apparatus (Boyden) (Fig 1).[19] Polyvinylpyrrolidone-free polycarbonate filters with 12-μm pores were placed between the upper and lower chambers. Conditioned medium, obtained by incubating the murine fibroblast cell line 3T3 isolated at the National Institutes of Health in serum-free DMEM containing 50 μg/mL of ascorbate overnight, was added to the lower chamber.[20] A cell suspension was prepared as described above, and an aliquot of this suspension containing 2.5×10^5 cells was added to the upper chamber. The apparatus was then incubated at 37°C in a humidified atmosphere of 95% air and 5% CO_2 for five hours. At the end of this period, the cells on the upper surface were mechanically removed with a cotton swab. The filters were then fixed in methanol and stained with a 10% solution of Giemsa stain. Cells that had migrated through the pores in the filters and were present on the lower surface were counted using the method described for adherence assays.

Fig 1.—Microchamber apparatus (Boyden). Cell suspension is added to upper chamber and chemoattractant is added to lower chamber. For invasion assays, perforated filter coated with matrigel is placed between chambers; uncoated filter is used in chemotaxis assays.

Assay for Adherence, Penetration, and Migration Through a Matrigel Barrier in Response to a Soluble Attractant (Chemoinvasion)

For chemoinvasion assays, the polyvinylpyrrolidone-free filters were coated with matrigel diluted to a final concentration of 500 μg/mL in cold distilled water.[20] The matrigel solution (100 μL) was applied to the filters, air-dried, and then reconstituted with serum-free DMEM for 30 minutes at 37°C. The filters were then placed in the microchamber apparatus with the matrigel layer facing the upper chamber. Assays were otherwise carried out as described above for chemotaxis. Cells that were present on the lower surface of the filter at the end of the assay were considered to have invaded.

Data were analyzed using the Student *t* test.

RESULTS

Characteristics of Colorectal Carcinoma Cell Lines

Eight established human colorectal carcinoma cell lines were employed in this study. These cell lines have been classified on the basis of criteria that relate to their degree of differentiation (Table). These criteria include carcinoembryonic antigen (CEA) expression, ability to form tumors in nude mice, histologic features of xenografts, and in vitro morphology (see Table for references). Poorly differentiated cell lines express little CEA, form tumors readily in nude mice, and exhibit the amorphous morphologic features characteristic of poorly differentiated tumors when grown as xenografts. In contrast, the moderately well-differentiated cell lines express abundant CEA, form tumors less readily in nude mice, and display an organized glandular morphologic condition when grown as xenografts. After evaluating the data presented in the Table, we classified the cell lines Clone A, MIP 101, CCL 222, and CCL 228 as poorly differentiated and the cell lines

CX-1, DLD-2, CCL 235, and CCL 238 as moderately well differentiated. The cell line DLD-2 is distinct from the other moderately well-differentiated cell lines because its xenograft histologic features resemble a signet ring carcinoma and it synthesizes large amounts of mucin in vivo and in vitro (G.W.D. and A.M.M., unpublished data, 1987).

Interactions of Colorectal Carcinoma Cell Lines With Matrigel

We examined the ability of the colorectal carcinoma cell lines described in the Table to interact with the reconstituted basement membrane matrix matrigel. The data obtained for the adherence of tumor cell lines on matrigel-coated surfaces are presented in Fig 2. The difference in adherence between the two differentiation classifications was striking. Adherence of the poorly differentiated cell lines Clone A, MIP 101, CCL 222, and CCL 228, as well as the moderately well-differentiated line DLD-2, was three to four times greater than adherence to the moderately well-differentiated cell lines CX-1, CCL 235, and CCL 238. The actual adherence values for the poorly differentiated cell lines were 186 ± 4.5 (mean ± SEM) and for the moderately well-differentiated lines, 65 ± 1.9. This difference was significant to a P value of .0001. The signet ring cell line DLD-2 adhered avidly to matrigel (228 ± 6.3). These numerical values for adherence were obtained from a larger number of experiments than the values reported in Fig 2.

To exclude the possibility that trypsin removed cell surface proteins that are involved in matrix interactions, we performed several additional experiments. Specifically, we observed that incubation of the cells for one to two hours at 37°C after trypsinization and before use in these assays did not produce a change in adherence as compared with their use immediately after trypsinization. Furthermore, similar adherence data were obtained when a divalent cation chelator, edetic acid, rather than trypsin, was used to detach the cells (data not shown). These observations confirm that trypsin treatment did not selectively remove surface-binding proteins for basement membrane components.

Pretreatment of tumor cells with cycloheximide before their use in the assays had no effect on adherence (data not shown). The difference in adherence between the cell lines presented in Fig 2, therefore, cannot be attributed to differences in their rates of de novo protein synthesis, especially the synthesis of basement membrane component–binding proteins. Nonspecific adherence to proteins by the tumor cells was determined in an assay using wells coated with BSA. For all cell lines, fewer than 1% of the number of cells that adhered to matrigel adhered to BSA.

The ability of colorectal tumor cells to adhere to matrigel correlated with their ability to spread on this substratum. The poorly differentiated cell lines Clone A and MIP 101 showed extensive cytoplasmic spreading following adherence. Fusiform elongation after adherence was seen for the poorly differentiated lines CCL 222 and CCL 228. Less-extensive spreading was noted following adherence of the moderately well-differentiated cell lines CX-1, CCL 235, and CCL 238. The moderately well-differentiated cell line DLD-2 did, however, spread extensively following adherence.

Motility of Colorectal Carcinoma Cells in Response to Chemical Attractants

We examined the ability of the colorectal carcinoma cell lines to migrate through a porous barrier in response to conditioned fibroblast medium as a chemoattractant (Fig 3). This chemoattractant was chosen because of its reproducible activity on a broad range of cell lines.[20] The cell lines Clone A and MIP 101 showed the greatest motility in this assay, although the remaining poorly differentiated and all the moderately well-differentiated cell lines were motile to some degree. The difference in motility between the moderately well-differentiated cell lines compared with Clone A and MIP 101 was significant (mean ± SEM, 9 ± 0.9 moderately well differentiated, 25 ± 1 Clone A, MIP 101, $P = .001$); however, the difference in motility between the moderately well-differentiated cell lines and the remaining poorly differentiated cell lines CCL 222 and CCL 228 was not significant (mean ± SEM, 7 ± 0.9 moderately well differentiated, 10 ± 1 CCL 222 and 228).

Invasion of Colorectal Carcinoma Cells Through a Matrigel Barrier in Response to a Soluble Attractant

These assays were performed to measure the ability of tumor cell lines to invade through matrigel in response to a chemoattractant. Invasion in this model is defined as the

Fig 2.—Adherence of cell lines to matrigel-coated surfaces. Matrigel was coated on tissue culture wells overnight and then reconstituted with media before use. Data were obtained from at least five separate experiments. Error bars represent standard error of mean.

Fig 3.—Migration of cell lines toward chemoattractant (chemotaxis). Chemotaxis assays were performed in microchamber apparatus (Boyden) using perforated filter between chambers. Conditioned 3T3 medium from National Institutes of Health, Bethesda, Md, was used as chemoattractant. Data were obtained from at least five separate experiments. Error bars represent standard error of mean.

ability of cells to adhere, penetrate, and migrate through a barrier layer of matrigel in response to a chemoattractant. Important parameters such as the thickness of the matrigel layer and time of the assay were determined empirically to yield the optimal resolution of invasion potential among the cell lines.[20] From the data presented in Fig 4, it is evident that all cell lines were invasive to some extent. The poorly differentiated cell lines Clone A, MIP 101, CCL 222, and CCL 228, however, were two to three times more invasive than the moderately well-differentiated cell lines CX-1, CCL 235, and CCL 238 (mean ± SEM, 30 ± 0.9 poorly differentiated vs 9 ± 0.7 moderately well differentiated, $P = .001$). DLD-2, which resembled the poorly differentiated cell lines in its ability to interact with matrigel, was also able to invade through a matrigel barrier in numbers similar to the poorly differentiated cells (mean ± SEM, 37 ± 3.0).

COMMENT

Recent studies have postulated that the ability of malignant cells to interact with basement membrane components

Fig 4.—Adherence, penetration, and migration through matrigel layer toward chemoattractant (invasion). Invasion assays were performed in microchamber apparatus (Boyden) using matrigel-coated filter between chambers. Conditioned 3T3 medium from National Institutes of Health, Bethesda, Md, was used as chemoattractant. Data were obtained from at least five separate experiments. Error bars represent standard error of mean.

is an important determinant of their invasive and metastatic behavior.[5-9] On the basis of these postulates, we were interested in determining whether the degree of differentiation is a factor that influences the ability of colorectal carcinoma cells to interact with the basement membrane. In our study, we have shown that the ability of colorectal carcinoma cell lines to adhere to and spread on matrigel, a basement membrane matrix, is related to their degree of cytodifferentiation.[14] The poorly differentiated colorectal carcinoma cell lines were two to three times more adherent and spread to a greater extent on matrigel than the moderately well-differentiated cell lines. An exception to this correlation was the moderately well-differentiated cell line DLD-2. This line, whose xenograft morphologic features resemble the notoriously aggressive signet ring carcinoma, adhered and spread on matrigel to the same extent as the poorly differentiated cell lines. This exception indicates that factors other than cytodifferentiation may contribute to the interaction of cells with the basement membrane. From these data, we can conclude that adherence to matrigel may effect a morphologic change, although this change does not seem to be mandatory for adherence to this material. Any potential significance of the extent and rate of spreading in vivo, however, may not be appreciated under the conditions chosen for thse assays.

The chemoinvasion assay developed by Albini et al[20] was used to measure the ability of the colorectal carcinoma cell lines to adhere, penetrate, and migrate through a matrigel layer in response to a chemoattractant. In this assay, the poorly differentiated cell lines, as well as the moderately differentiated line DLD-2, were two to three times more invasive than the other moderately well-differentiated lines. From these data, combined with the adherence data, we conclude that the ability of a tumor cell to adhere to the basement membrane correlates with its ability to invade through a basement membrane matrix. In contrast, the ability to invade through a basement membrane did not correlate with the ability of these cells to migrate toward a chemoattractant (chemotaxis) in the absence of the basement membrane. Chemotaxis by these cells, therefore, may be a reflection of their intrinsic motility but it does not seem to be a relevant measure of their motility following adherence to the basement membrane.

The data presented in this study complement one currently accepted model for tumor invasion.[8,9] In this model, the initial requisite step for invasion is tumor cell adherence, via cell surface receptors, to a basement membrane component such as laminin. This attachment may prompt the synthesis and secretion of proteolytic enzymes that are necessary for degradation of the basement membrane. Migration through the degraded basement membrane may also be stimulated by adherence to basement membrane components as well as by soluble motility factors.[21,22] On the basis of this model, we believe that the increased invasive potential of the poorly differentiated colorectal carcinoma cell lines, as well as the moderately well-differentiated line DLD-2, is, in part, related to their increased ability to adhere and spread on basement membranes. In addition, their ability to migrate through the basement membrane is enhanced by adherence to basement membrane components regardless of their degree of differentiation.

We believe it is premature to establish the correlation between adherence and invasion too strongly. Invasion is a complex, multivariable process. Other basic tenets of the invasion model need to be evaluated for these cell lines. For example, it is important to determine whether adherence-related enzyme secretion or stimulated motility vary with cytodifferentiation. Nevertheless, the ability of the colorectal carcinoma cells to interact with basement membranes may, in part, explain the more aggressive clinical behavior of poorly differentiated colorectal carcinomas as compared with well-differentiated tumors. Furthermore, reagents that identify differences in cell surface receptors for basement membrane components may be useful for distinguishing more clinically aggressive tumors among those with a similar histopathologic appearance.

This work was supported by grant CA 44707 from the National Institutes of Health. Henry Sears, MD, provided editorial assistance and Laura Edwards provided the statistical analysis involved in preparation of this manuscript. Dr Mercurio is the recipient of an American Cancer Society Junior Faculty Award.

Daniel Dexter, PhD, from E. I. DuPont DeNemours & Co, Wilmington, Del, provided the Clone A and DLD-2. The MIP 101 was provided by Richard Niles, PhD, Mallory Gastrointestinal Research Laboratory, Boston. The Englebreth-Holm-Swarm sarcoma was a gift from Herbert Kupchuck, PhD, Boston University.

Discussion

Q I think your results that evaluate adherence and invasiveness in vitro correlate with generally accepted principles of histology and aggressiveness. I had several questions; the first relates to the agents that may identify these cell surface receptors. Do you have monoclonal antibodies or other agents that you can use to identify these receptors or correlate them with other products of these cells, such as CEA, for example?

A There are a few polyclonal antibodies made against the receptors that are available at the National Institutes of Health. In addition, Yumada's group there has cloned some of the sequence in the receptor. They've actually made a monoclonal antibody to fusion protein, so reagents are there and potentially useful.

Q The second question is can you correlate these in vitro results with in vivo results, for example, a cecal injection model or other models using these particular cell lines?

A That's a good question. We've wanted to use some of the antibodies we have on some of our xenograph sections to see whether we can. Leota has done some preliminary work at the National Institutes of Health and showed in pathologic specimens from human tumors that there is increased expression of receptors in some metastatic deposits in more invasive tumors.

Q Back in October at the forum, your group reported on human tumors and epidermal growth factor-receptor activity in primary and metastatic sites. Have you looked at any of the primary or metastatic tumors from patients as to their ability to adhere?

A We have not. Actually, we limited our work to using only commercially available cell lines, but that's a good point. Everyone knows the obvious limitations of in vitro cell lines.

Q Do you have any information on proteases, collagenases, plasmin, or plasminogen in the systems?

A No. Some other groups have looked at it, and there was a report in 1986 in which adherence stimulated the production of type 4 collagenase by tumor cells, so there is some work done. There are difficulties with experimental design in looking at proteases. I think that is why we haven't seen more about that.

Q One more thing—it's not just chemoattraction, is it? Is there any chemokinetic activity? Is it increased penetration in general or is it specific in response to a chemoattractant?

A It's hard to say. Some of it is a response to chemoattractant. Some of the laminin lysis fragments are very active as chemoattractants.

DEFINING A NEW STANDA

RD* FOR EMPIRIC THERAPY

For Infection Following
Complicated Abdominal Surgery

BETTER THAN AMINOGLYCOSIDE COMBINATIONS FOR MOST PATIENTS

For These Reasons...

- ☐ Gram-negative coverage of an aminoglycoside plus
- ☐ Gram-positive coverage of cefazolin plus
- ☐ Anaerobic coverage of clindamycin or metronidazole plus
- ☐ Enterococcal coverage of ampicillin plus
- ☐ Tolerability profile characteristic of beta-lactam antibiotics

...PRIMAXIN Is a Better Choice for Empiric Therapy

Coverage of specified agents is based upon the Microbiology Section of the Prescribing Information as published in the 1988 *Physicians' Desk Reference*®

Data available from Merck Sharp & Dohme, West Point, PA 19486.

PRIMAXIN is contraindicated in patients who have shown hypersensitivity to any component of this product. Before initiating therapy with PRIMAXIN, careful inquiry should be made concerning previous hypersensitivity reactions to penicillins, cephalosporins, other beta-lactams, and other allergens. If an allergic reaction to PRIMAXIN occurs, discontinue the drug. Serious hypersensitivity reactions may require epinephrine and other emergency measures.

In vitro activity does not necessarily imply *in vivo* effectiveness.

*when indicated organisms are suspected at indicated sites

INTRAVENOUS

PRIMAXIN®

(Imipenem-Cilastatin Sodium/MSD)

Please see Brief Summary of Prescribing Information on following page.

INTRAVENOUS

PRIMAXIN®

(Imipenem-Cilastatin Sodium/MSD)

Contraindications: PRIMAXIN is contraindicated in patients who have shown hypersensitivity to any component of this product.

Warnings: SERIOUS AND OCCASIONALLY FATAL HYPERSENSITIVITY (anaphylactic) REACTIONS HAVE BEEN REPORTED IN PATIENTS RECEIVING THERAPY WITH BETA LACTAMS. THESE REACTIONS ARE MORE APT TO OCCUR IN PERSONS WITH A HISTORY OF SENSITIVITY TO MULTIPLE ALLERGENS.

THERE HAVE BEEN REPORTS OF PATIENTS WITH A HISTORY OF PENICILLIN HYPERSENSITIVITY WHO HAVE EXPERIENCED SEVERE HYPERSENSITIVITY REACTIONS WHEN TREATED WITH ANOTHER BETA LACTAM. BEFORE INITIATING THERAPY WITH 'PRIMAXIN,' CAREFUL INQUIRY SHOULD BE MADE CONCERNING PREVIOUS HYPERSENSITIVITY REACTIONS TO PENICILLINS, CEPHALOSPORINS, OTHER BETA LACTAMS, AND OTHER ALLERGENS. IF AN ALLERGIC REACTION TO 'PRIMAXIN' OCCURS, DISCONTINUE THE DRUG. SERIOUS HYPERSENSITIVITY REACTIONS MAY REQUIRE EPINEPHRINE AND OTHER EMERGENCY MEASURES.

Pseudomembranous colitis has been reported with virtually all antibiotics, including PRIMAXIN; therefore it is important to consider its diagnosis in patients who develop diarrhea in association with antibiotic use. This colitis may range in severity from mild to life threatening.

Mild cases of pseudomembranous colitis may respond to drug discontinuance alone. In more severe cases, management may include sigmoidoscopy, appropriate bacteriological studies, fluid, electrolyte, and protein supplementation, and the use of a drug such as oral vancomycin, as indicated. Isolation of the patient may be advisable. Other causes of colitis should also be considered.

Precautions: *General*—CNS adverse experiences such as confusional states, myoclonic activity, and seizures have been reported during treatment with PRIMAXIN, especially when recommended dosages were exceeded. These experiences have occurred most commonly in patients with CNS disorders (e.g., brain lesions or history of seizures) and/or compromised renal function. However, there have been reports of CNS adverse experiences in patients who had no recognized or documented underlying CNS disorder or compromised renal function.

Patients with severe or marked impairment of renal function, whether or not undergoing hemodialysis, had a higher risk of seizure activity when receiving maximum recommended doses than those with no impairment of renal function; therefore, maximum recommended doses should be used only where clearly indicated (see DOSAGE AND ADMINISTRATION).

Patients with creatinine clearances of ≤5 mL/min/1.73 m^2 should not receive PRIMAXIN unless hemodialysis is instituted within 48 hours.

For patients on hemodialysis, PRIMAXIN is recommended only when the benefit outweighs the potential risk of seizures.

Close adherence to the recommended dosage and dosage schedules is urged, especially in patients with known factors that predispose to convulsive activity. Anticonvulsant therapy should be continued in patients with known seizure disorders. If focal tremors, myoclonus, or seizures occur, patients should be evaluated neurologically, placed on anticonvulsant therapy if not already instituted, and the dosage of PRIMAXIN re-examined to determine whether it should be decreased or the antibiotic discontinued.

As with other antibiotics, prolonged use of PRIMAXIN may result in overgrowth of nonsusceptible organisms. Repeated evaluation of the patient's condition is essential. If superinfection occurs during therapy, appropriate measures should be taken. While PRIMAXIN possesses the characteristic low toxicity of the beta-lactam group of antibiotics, periodic assessment of organ system function during prolonged therapy is advisable.

Drug Interactions—Since concomitant administration of PRIMAXIN and probenecid results in only minimal increases in plasma levels of imipenem and plasma half-life, it is not recommended that probenecid be given with PRIMAXIN.

PRIMAXIN should not be mixed with or physically added to other antibiotics. However, PRIMAXIN may be administered concomitantly with other antibiotics, such as aminoglycosides.

Carcinogenesis, Mutagenesis, Impairment of Fertility—Gene toxicity studies were performed in a variety of bacterial and mammalian tests *in vivo* and *in vitro*. The tests were: V79 mammalian cell mutation assay (PRIMAXIN alone and imipenem alone), Ames test (cilastatin sodium alone), unscheduled DNA synthesis assay (PRIMAXIN), and *in vivo* mouse cytogenicity test (PRIMAXIN). None of these tests showed any evidence of genetic damage.

Reproduction tests in male and female rats were performed with PRIMAXIN at dosage levels up to 8 times the usual human dose. Slight decreases in live fetal body weight were restricted to the highest dosage level. No other adverse effects were observed on fertility, reproductive performance, fetal viability, growth, or postnatal development of pups. Similarly, no adverse effects on the fetus or on lactation were observed when PRIMAXIN was administered to rats late in gestation.

Pregnancy—Pregnancy Category C: Teratogenicity studies with cilastatin sodium in rabbits and rats at 10 and 33 times the usual human dose, respectively, showed no evidence of adverse effect on the fetus. No evidence of teratogenicity or adverse effect on postnatal growth or behavior was observed in rats given imipenem at dosage levels up to 30 times the usual human dose. Similarly, no evidence of adverse effect on the fetus was observed in teratology studies in rabbits with imipenem at dosage levels at the usual human dose.

Teratology studies with PRIMAXIN at doses up to 11 times the usual human dose in pregnant mice and rats during the period of major organogenesis revealed no evidence of teratogenicity.

Data from preliminary studies suggest an apparent intolerance to PRIMAXIN (including emesis, inappetence, body weight loss, diarrhea, and death) at doses equivalent to the average human dose in pregnant rabbits and cynomolgus monkeys that is not seen in nonpregnant animals in these or other species. In other studies, PRIMAXIN was well tolerated in equivalent or higher doses (up to 11 times the average human dose) in pregnant rats and mice. Further studies are under way to evaluate these findings.

There are, however, no adequate and well-controlled studies in pregnant women. PRIMAXIN should be used only if the potential benefit justifies the potential risk to the fetus.

Nursing Mothers—It is not known whether this drug is excreted in human milk. Because many drugs are excreted in human milk, caution should be exercised when PRIMAXIN is administered to a nursing woman.

Pediatric Use—Safety and effectiveness in infants and children below 12 years of age have not yet been established.

Adverse Reactions: PRIMAXIN is generally well tolerated. Many of the 1,723 patients treated in clinical trials were severely ill and had multiple background diseases and physiological impairments, making it difficult to determine causal relationship of adverse experiences to therapy with PRIMAXIN.

Local Adverse Reactions—Local adverse clinical reactions that were reported as possibly, probably, or definitely related to therapy with PRIMAXIN were: phlebitis/thrombophlebitis (3.1%), pain at the injection site (0.7%), erythema at the injection site (0.4%), vein induration (0.2%), infused vein infection (0.1%).

Systemic Adverse Reactions—The most frequently reported systemic adverse clinical reactions that were reported as possibly, probably, or definitely related to PRIMAXIN were: nausea (2.0%), diarrhea (1.8%), vomiting (1.5%), rash (0.9%), fever (0.5%), hypotension (0.4%), seizures (0.4%) (see PRECAUTIONS), dizziness (0.3%), pruritus (0.3%), urticaria (0.2%), somnolence (0.2%).

Additional adverse systemic clinical reactions reported as possibly, probably, or definitely drug related occurring in less than 0.2% of the patients or reported since the drug was marketed are listed within each body system in order of decreasing severity: *Gastrointestinal*—pseudomembranous colitis (see WARNINGS), hemorrhagic colitis, gastroenteritis, abdominal pain, glossitis, tongue papillar hypertrophy, heartburn, pharyngeal pain, increased salivation; *CNS*—encephalopathy, tremor, confusion, myoclonus, paresthesia, vertigo, headache, psychic disturbances; *Special Senses*—transient hearing loss in patients with impaired hearing, tinnitus; *Respiratory*—chest discomfort, dyspnea, hyperventilation, thoracic spine pain; *Cardiovascular*—palpitations, tachycardia; *Renal*—oliguria/anuria, polyuria; *Skin*—erythema multiforme, facial edema, flushing, cyanosis, hyperhidrosis, skin texture changes, candidiasis, pruritus vulvae; *Body as a Whole*—polyarthralgia, asthenia/weakness.

Adverse Laboratory Changes—Adverse laboratory changes without regard to drug relationship that were reported during clinical trials or reported since the drug was marketed were: *Hepatic*—increased SGPT, SGOT, alkaline phosphatase, bilirubin, and LDH; *Hemic*—increased eosinophils, positive Coombs test, decreased WBC and neutrophils, including agranulocytosis, increased WBC, increased platelets, decreased platelets, decreased hemoglobin and hematocrit, increased monocytes, abnormal prothrombin time, increased lymphocytes, increased basophils; *Electrolytes*—decreased serum sodium, increased potassium, increased chloride; *Renal*—increased BUN, creatinine; *Urinalysis*—presence of urine protein, urine red blood cells, urine white blood cells, urine casts, urine bilirubin, and urine urobilinogen.

NOTE: Due to the high antimicrobial activity of PRIMAXIN, it is recommended that the maximum total daily dosage not exceed 50 mg/kg/day or 4.0 g/day, whichever is lower.

How Supplied: PRIMAXIN is supplied as a sterile powder mixture in vials, infusion bottles, and single-dose ADD-Vantage®† vials containing imipenem anhydrous and cilastatin sodium as follows: 250 mg imipenem equivalent and 250 mg cilastatin equivalent; 500 mg imipenem equivalent and 500 mg cilastatin equivalent.

Caution: The suspension from vials is not for direct infusion.

The Desmoid Tumor

Not a Benign Disease

Mitchell C. Posner, MD; Man H. Shiu, MD; James L. Newsome, MD; Steven I. Hajdu, MD; Jeffrey J. Gaynor, PhD; Murray F. Brennan, MD

• The necessity of aggressive therapy for desmoid tumors has not been clearly established. To evaluate the therapeutic value of adequate resection and radiation therapy, we conducted a retrospective study of 138 patients treated from 1965 through 1984. Univariate analysis revealed five factors predictive of local failure: (1) age between 18 and 30 years, (2) presentation with recurrent disease, (3) partial or limited margin excision, (4) tumor at or close to the microscopic margin of resection, and (5) radiation therapy not administered for gross residual disease. Multivariate analysis identified two of these factors as having independent predictive value for recurrence: (1) presentation with recurrent disease and (2) less-than-adequate margins of resection. The five-year survival probability was 92%, but 11 of the 138 patients died as a consequence of locally uncontrolled tumor. These findings confirm that desmoid tumors are malignant soft-tissue neoplasms that warrant aggressive therapy.
(*Arch Surg* 1989;124:191-196)

Desmoid tumors are relatively rare malignant soft-tissue neoplasms derived from fascial or musculoaponeurotic structures.[1] Their classification as low-grade fibrosarcomas is based primarily on a marked propensity for local invasion.[2-6] In contrast to other soft-tissue sarcomas, the necessity for aggressive therapy of desmoid tumors has not been clearly established. Failure to recognize their malignant local behavior has led to conflicting recommendations regarding surgical management. The role of radiation therapy in the management of this neoplasm is poorly defined. In an attempt to evaluate the therapeutic value of adequate resection and the potential benefit of adjunctive radiation therapy and to define factors that influence local tumor control, a retrospective analysis was undertaken.

PATIENTS AND METHODS

Examination of the tumor registry at Memorial Sloan-Kettering Cancer Center, New York, between the years 1965 and 1984 identified 185 patients with a presumptive diagnosis of desmoid tumor or low-grade fibrosarcoma. Following histologic review of all slides, 144 were classified as desmoid tumors. One hundred thirty-eight charts were available for review. Seven patients were excluded due to a lack of follow-up information. The remaining 131 patients form the basis for this report.

Accepted for publication July 15, 1988.

Reprint requests to Memorial Sloan-Kettering Cancer Center, 1275 York Ave, New York, NY 10021 (Dr Brennan).

Clinicopathologic Data

Patient demographics extracted from chart analysis included the following: age, sex, symptoms, possible causal factors, previous surgical or adjuvant treatment, and presentation (untreated or recurrent). Tumor characteristics examined were the site, size, depth, and invasion of bone or major neurovascular structures. Tumor size was determined by measurement of either a pathologic specimen or an intraoperative lesion. The classification of tumor penetration as either superficial or deep was dependent on the tumor's anatomic relationship to the superficial fascia. Bone or neurovascular invasion was considered present when identified on gross examination and confirmed microscopically.

The pathologic diagnosis of desmoid tumor in all patients was established following critical review of the available tissue slides by one of the authors (S.I.H.). Histologically, desmoid tumors are composed of uniform collagenous fibrocytes in broad bundles and fascicles. The neoplastic cells are arranged in a one-directional spreading pattern without interruption or necrosis (Fig 1). The intercellular matrix is abundant, is often scarlike, and stains uniformly positive with trichrome stain. The overall appearance of desmoid tumors is that of a well-differentiated "mature" fibrous neoplasm that shows no cellular pleomorphism or mitotic activity. Direct invasion of contiguous structures by fingerlike projections of tumor is frequently demonstrated (Fig 2).

Surgical Treatment

Treatment data obtained included the surgical procedure, scope of resection, margins of resection, and adjuvant therapy. The *scope of resection* was determined by careful review of the operative note and categorized as follows: (1) Partial excision refers to incomplete resection or intralesional debulking. (2) Limited margin resection describes removal of all gross tumor with only a scant margin (millimeters) of uninvolved surrounding tissue. Although the surgeon's intent was complete tumor excision, microscopic examination invariably demonstrated disease at or close to the margin following limited margin resection. (3) Wide margin and compartment resection entails monobloc soft-tissue resection encompassing the entire tumor and its ramifications, with a variable margin of normal surrounding tissue and no exposure of the tumor during extirpation.

The *margin of resection* was then classified as adequate, marginal, or inadequate based on pathologic examination. Adequate resection referred to a wide margin of uninvolved tissue on all sides and no evidence of tumor on microscopic examination of the margin. The resection was deemed marginal if the tumor approximated the surgical margin (ie, was within millimeters). Microscopic evidence of tumor at the resection margin confirmed an inadequate resection.

Fig 1.—Desmoid tumor (low-grade fibrosarcoma) composed of uniform collagenous fibrocytes (hematoxylin-eosin, original magnification ×450).

Fig 2.—Desmoid tumor (low-grade fibrosarcoma) invading medullary cavity of bone (hematoxylin-eosin, original magnification ×170).

Radiation Therapy

The intent of radiotherapy was categorized as either primary therapy or as an adjunct to surgery. The following techniques were used for delivery of radiation therapy during the study period: (1) external beam, (2) temporary implant of iridium 192 sources via afterloading catheters, and (3) permanent interstitial implant of iodine 125 seeds (brachytherapy). The brachytherapy technique has been previously described.[7-9] In selected patients, multiple techniques were employed.

Statistical Analysis

The study end points were local recurrence and death. Follow-up was obtained from recent chart documentation, when available, or by personal contact with the patient or responsible physician. The probability of local recurrence and overall survival curves were generated according to the method of Kaplan and Meier.[10] Univariate analysis comparing recurrence rates between patient subgroups was performed using the log-rank test of statistical significance.[11] Multivariate analysis using the Cox model of stepwise linear regression[12] was applied to identify independent factors that significantly influenced local recurrence.

Patients

There were 80 females (61%) and 51 males (39%), a female-to-male ratio of 1.6:1. The median age was 29 years (range, 6 to 73 years). Seventy-eight patients were referred for treatment of their initial tumor, 67 with their tumor intact or biopsied and 11 who had recently undergone resection, with residual disease on either microscopic or gross examination. Fifty-three patients presented with locally recurrent disease. Administration of radiotherapy some time prior to presentation at our center was documented in 11 patients.

Sixty-seven patients (51%) had tumors located at an extremity site, 19 (15%) at a retroperitoneal site, 16 (12%) in the abdominal wall, 13 (10%) in the chest wall, and ten (8%) in the head and neck. Gardner's syndrome was described in four patients, and two patients had visceral desmoid tumors.

One hundred twenty-eight patients had curative attempts at resection of their primary tumor, two had biopsy only, and one patient with Gardner's syndrome who had extensive tumor involvement of the abdominal wall and small-bowel mesentery underwent palliative resection. The *scope of resection* was categorized as wide margin or compartmental in 64 patients, limited margin in 40 patients, and partial excision in 24 patients. The *resection margin* was considered adequate in 47 patients (37%) and less than adequate in 81 patients (63%). Of those whose resection margin was deemed less than adequate, 41 showed tumor approximating the surgical margin, albeit microscopically negative, and 40 showed tumor at the resection margin. Radiotherapy was administered to 15 patients with positive margins. Five patients were given radiation therapy as an adjunct to complete tumor extirpation.

Fig 3.—Probability of local recurrence in patients treated with curative intent (n = 128). Kaplan-Meier plot. Local failure rate was 37% at five years.

RESULTS

Analysis of local recurrence and survival data is based only on patients who underwent resection for cure. The median follow-up for the 128 patients who underwent curative attempts at resection was 7.3 years.

Local Tumor Control

Eighty-two of the 128 tumors were successfully controlled following definitive surgical treatment with or without radiation therapy at our center. The probability of local failure is estimated to be 37% at five years (Fig 3). Local recurrence occurred in 46 patients, with a median time to recurrence of 15 months (range, three to 64 months). Approximately 80% of the recurrences were observed to occur within the first two years following resection (Fig 3). Distant failure in conjunction with locally recurrent disease was seen in one patient with a large retroperitoneal lesion that was unsuccessfully resected multiple times. Pathologically confirmed lung metastases developed eight years following the initial attempt at resection, and the patient died one year later as a result of disease progression.

Fig 5.—Rate of local recurrence in patients with adequate margins (squares, n = 47), marginal resection margins (hatch marks, n = 41), and inadequate margins (asterisks, n = 40) of resection. $P = .0002$ for patients with adequate margins compared with those with less-than-adequate margins. Kaplan-Meier plots.

Clinicopathologic and Treatment Factors Influencing Local Failure

Univariate analyses of the influence of clinicopathologic and treatment variables on the rate of local recurrence are depicted in Table 1.

Of the clinicopathologic factors, only age and presentation with or without locally recurrent disease significantly influenced the rate of local recurrence. Desmoid tumors predominate in young age groups (70% under 45 years), and those less than 30 years of age have an increased rate of local recurrence (43% vs 27%). When this variable is analyzed with respect to three chronologic groups (<18, 18 to 30, and >30 years), patients who are between 18 and 30 years of age are at significantly increased risk of local failure ($P = .006$). The presence of symptoms, sex, tumor size or location, depth of penetration, and bone or neurovascular invasion had no demonstrable impact on local recurrence.

Of the treatment factors, *scope of resection* significantly influenced subsequent local recurrence (Fig 4). Wide margin or compartment resection was associated with a prolonged disease-free interval compared with less extensive procedures ($P = .02$). As expected, conservative resection was more likely to result in less-than-adequate margins of resection than wide margin or compartment resection (100% vs 27%).

An adequate *resection margin*, as determined by path-

Fig 6.—Effect of radiation therapy on rate of local recurrence of gross residual disease in patients with (squares, n = 9) and without (hatch marks, n = 11) radiation therapy. $P = .02$. Kaplan-Meier plots.

Fig 7.—Effect of radiation therapy on rate of local recurrence in patients who underwent partial tumor excision (squares, n = 9) compared with patients who underwent wide margin or compartment resection with adequate margins (hatch marks, n = 47). $P = .8$.

ologic examination, significantly reduced local recurrence compared with less-than-adequate resection margins (Fig 5), either marginal or inadequate. However, no difference in local recurrence rates was demonstrated between the marginal and inadequate margin subsets ($P = .6$).

Although the numbers are small, radiotherapy appeared to improve local control following incomplete tumor excision. Radiation therapy for gross residual tumor following inadequate resection significantly reduced the rate of local recurrence (Fig 6). In fact, there was no significant difference in local failure for patients who underwent radiation therapy following partial tumor excision compared with those who had wide margin or compartment resections with an adequate margin of resection (the most favorable group, Fig 7). Radiation therapy administered for minimal disease left behind following inadequate resection did not improve local control. However, the majority of patients who received radiotherapy for minimal residual disease had previous recurrences.

Multivariate Analysis of Factors Influencing Local Failure

The covariate pairs of prognostic variables listed in Table 1 were entered into the Cox model of proportional hazards for multivariate analysis. Of the five significant pairs identified by univariate analysis, only two were found to be independently predictive of recurrence by the model: (1) less-than-adequate margin of resection ($P = .0002$) and (2) presentation with recurrent disease ($P = .02$). The Cox model coefficients predict a fourfold increase in the rate of local failure with a less-than-adequate margin of resection and a twofold increase due to presentation with recurrent disease. If both unfavorable factors are present, the model predicts an eightfold increase in the rate of local recurrence.

Treatment of Local Failure

Thirty-three of the 46 patients with failed initial treatment at Memorial Hospital underwent further resection with curative intent. Nine patients received radiotherapy in addition in surgery. Twenty-eight patients (85%) reresected for cure are alive without evidence of disease, with a median follow-up of 70 months (range, two to 236 months).

Survival

The overall five-year survival probability of patients treated with curative intent was 92% according to the Kaplan-Meier curve (Fig 8). Four patients died of causes unrelated to their tumors. Eleven patients died of disease,

Fig 8.—Overall probability of survival in patients treated with curative intent (n = 128). Kaplan-Meier plot. There was 92% probability of five-year survival.

with a median time to death ranging from two to 136 months following treatment. Inexorable local tumor progression led to compromise of major organ functions or obstruction of the aerodigestive tract, frequently accompanied by sepsis and malnutrition. The ultimate causes of death are listed in Table 2. All patients dead of disease had nonextremity lesions for which the scope of resection was either partial excision or limited margins, and the pathologic margins of resection were less than adequate in all. Only one patient who died received radiotherapy as a method for control of residual disease visible on gross or microscopic examination. The tumor site was retroperitoneal in four patients, the abdominal wall in two patients, the head and neck in two patients, and the chest wall in one patient. The two remaining patients had Gardner's syndrome with extensive involvement of the abdominal wall and small-bowel mesentery.

COMMENT

The desmoid tumor remains a poorly understood neoplasm as a result of disparate reports regarding pathologic classification, tumor biology, and treatment alternatives. Many early reports documented the relentless local invasion of these tumors.[2,5,6,13,14] The term *aggressive fibromatosis* has, however, been applied as a diagnostic label for these neoplasms. At times, such a diagnosis may give an erroneous sense of security to the treating physician. Desmoid tumors are considered at our institution to be malignant soft-tissue tumors that have a predilection for

Table 2.—Causes of Death Following Treatment

Patient No.	Site	Initial Treatment	Cause of Death
1	Tonsillar fossa, neck	Commando procedure	Local disease progression, tracheal compression
2	Neck, shoulder girdle	Local excision	Local disease progression, intrathoracic invasion, superior vena cava syndrome
3	Chest wall	Chest wall resection	Local disease progression, intrathoracic and intra-abdominal invasion, tracheal compression
4	Abdominal wall, pelvis	Abdominal wall resection, hemipelvectomy	Local disease progression, fecal fistula, sepsis
5	Abdominal wall	Abdominal wall resection	Local disease progression, intra-abdominal invasion, small-bowel and colonic fistulas, pulmonary fibrosis secondary to bleomycin therapy
6	Abdominal wall, retroperitoneum	Abdominal wall resection of retroperitoneal mass, right-sided hemicolectomy, partial gastrectomy, small-bowel resection	Local disease progression, intra-abdominal invasion, malnutrition
7	Retroperitoneum	Resection of retroperitoneal mass, external beam and interstitial radiation	Local and distant disease progression, intra-abdominal invasion, pulmonary metastases
8	Retroperitoneum	Resection of retroperitoneal mass, partial cystectomy, sigmoid colectomy	Fistula, sepsis
9	Retroperitoneum	Resection of entire small bowel, small-bowel transplant	Sepsis, malnutrition, homograft rejection
10	Gardner's syndrome, abdominal wall	Abdominal wall resection, small-bowel resection	Local disease progression, chest wall and intra-abdominal invasion, duodenal fistula, sepsis, hepatic and renal failure
11	Gardner's syndrome, abdominal wall	Subtotal colectomy, resection of abdominal wall	Local disease progression, small-bowel fistula, malnutrition

aggressive local behavior and that rarely metastasize.[1,15] This classification, although not universally accepted, is corroborated by this in-depth retrospective analysis. The Task Force for Soft Tissue Sarcomas of the American Joint Committee for Cancer Staging and End Results Reporting also regarded these tumors as malignant neoplasms, referring to them as nonmetastasizing low-grade fibrosarcomas.[16] In addition, the American Cancer Society lists the desmoid tumor as a low-grade soft-tissue sarcoma,[17] and an expert panel[18] agreed on its behavior as such. The pronounced tendency toward local failure and potential for subsequent mortality, especially when managed inappropriately, confirms that the desmoid tumor is not a benign disease.

The natural history of untreated desmoid tumors, in general, is slow, relentless growth with invasion of contiguous structures. However, a small number of patients with inadequate excision may have stabilization and/or regression of their tumors. In the present series, 29% of patients who underwent partial excision were without evidence of disease at last follow-up. As mentioned above, distant tumor dissemination is uncommon[1] but did occur in a single patient. Transformation to a different histologic type, a process described by others, was not observed.

Aggressive resection in an effort to obtain as wide a margin of uninvolved surrounding tissue as possible is clearly the single most important determinant of a successful outcome. This finding, based on a retrospective analysis of 131 patients, corroborates our previous conviction[1,2,3,6] and that of others.[19,20] A recommendation of wide margin resection is in direct contradistinction to that of other authors, who do not recognize the malignant behavior of desmoid tumors and espouse conservative simple excision.[21-24] However, it is clear that marginal resection in the present series offered no advantage over surgical excision that was inadequate on gross examination. The resection should therefore be considered inadequate when the margin of resection on microscopic examination either is involved by tumor or approximates tumor. Presumably, undetected residual microscopic disease is present at the tumor bed site following excision with "minimal" surgical margins. Similarly, when a desmoid tumor recurs, attempts at curative resection of locally recurrent disease are warranted; observations in this study indicate that these patients can still be salvaged by appropriate surgery.

The use of radiotherapy either as a primary definitive treatment for control of residual disease or as an adjunct to surgical excision is less clear. There are conflicting reports regarding the efficacy of this treatment modality. Control of residual tumor visible on both microscopic and gross examination by radiation delivered by either the brachytherapy technique or external beam has been demonstrated.[20,25] In addition, partial or complete tumor regression when radiation is used as an alternative to surgery has been reported.[20,26] Other reports showed no benefit or a deleterious effect with the use of radiotherapy.[22] Our data suggest the possibility of prolonged local control in patients who undergo radiation following incomplete tumor extirpation. However, the numbers are small and further evaluation is necessary.

Standard chemotherapeutic agents have been sporadically used, but reports are anecdotal and results inconclu-

sive. The role of hormonal therapy and other unconventional chemotherapeutic agents (nonsteroidal anti-inflammatory drugs, theophylline, chlorothiazide, etc) are similarly ill defined.

Controversy regarding the appropriate management of desmoid tumors may have resulted from misconceptions regarding their pathologic classification and clinical behavior. Benign fibromatoses do not have the histologic characteristics of desmoid tumors described in this study. We believe desmoid tumors should be recognized as low-grade soft-tissue sarcomas with a marked tendency toward local invasion. Failure to acknowledge this malignant behavior leads to conservative and inadequate surgical therapy with resultant local failure and the potential for subsequent mortality. Aggressive attempts at resection are warranted not only for initial definitive treatment but also to salvage patients who have recurrences. When an adequate margin of resection cannot be obtained due to the need to preserve vital anatomic structures, the addition of radiation therapy may provide the necessary "margin" to prevent local failure. The desmoid tumor is not a benign disease, and clinicians as well as pathologists should make every effort to distinguish it from fibromatoses. Proper management of desmoid tumors requires aggressive resectional techniques and, in select instances, adjunctive therapy to ensure a favorable outcome.

Discussion

Q I would like to present a different viewpoint of this disease and its treatment. We have spent a lot of time reviewing its pathologic characteristics in our hospital. Low grade fibrosarcoma does have up to one mitosis per ten high-power fields. One virtually never sees mitoses in a desmoid tumor, but the difference is that desmoid tumors are much much more vascular than low-grade fibrosarcomas. Low-grade fibrosarcomas rarely respond to radiation, but desmoid tumors respond beautifully to radiation. There have been several reports of radiotherapists treating desmoid tumors without any surgery at all with excellent long-term results. We do as wide an excision as we can, but we never mutilate the patient, and we do not worry about free margins. We always use radiotherapy after primary resection, and we rarely if ever see any recurrences in our own patients.

The real problem is that people undergo limited resections and then get recurrence after recurrence after recurrence and only then get radiation in tissues that are difficult to treat, and then these patients are in trouble. Patients with this disease who get radiation after the first treatment do the best, especially those with Gardner's syndrome, who have the bowel problems that most of your complications and deaths were associated with. I agree that desmoid tumor is not a benign disease, but it should never be overtreated with surgical resection, because this is unnecessary.

A The desmoid tumor appears to be very ubiquitous. Our data show that in some patients radiotherapy does have some value. However, there was a subset of patients who had minimal disease left behind following resection who did not respond at all to radiotherapy. I agree that our intent should be to avoid mutilating patients, and in patients with extremity lesions, one can continue to do resections with limb salvage without any possibility of death. In patients with lesions at other sites, such as the head and neck and abdominal wall, desmoid tumors appear to need aggressive resection with or without radiotherapy.

Q Regardless of how skillful or aggressive you are, there will occasionally be a desmoid tumor that is nonresectable. I have had two such patients under my care, and both responded to the administration of tamoxifen citrate. You did not mention this possibility, and it may not be common knowledge. Both patients were women, and neither had undergone irradiation before the administration of tamoxifen was started.

A There are anecdotal reports in the literature of the use of various nontraditional chemotherapeutic agents, such as tamoxifen, theophylline, and hydrochlorothiazide, with differing results. In this analysis I could not find any pattern, and that is why I did not mention it.

Q What about spontaneous regression? This is the mysterious thing about desmoid tumors, and it has been reported before. One of my patients had an advanced desmoid tumor that involved the brachial plexus and the intervertebral foramina that disappeared completely, and it has been gone for over 12 years. This boy did not take anti-inflammatory drugs. Two other patients had a marked decrease in the size of their tumors associated with the use of nonsteroidal anti-inflammatory drugs. Have you had any experience with spontaneous regression?

A There is no question that desmoid tumors can act very strangely. Approximately 20% of our patients who had a resection that was inadequate on gross examination did not have recurrences after long-term follow up. Some patients do have spontaneous regression. I do not know what is behind that.

Scar or Recurrent Rectal Cancer

Positron Emission Tomography Is More Helpful for Diagnosis Than Immunoscintigraphy

Peter Schlag, MD; Burkhard Lehner, MD; Ludwig G. Strauss, MD; Peter Georgi, MD; Christian Herfarth, MD

• We used positron emission tomography and fludeoxyglucose F 18 to assess metabolic activity of a pelvic mass in 18 patients who had suspected recurrent rectal cancer. Computed tomography could not differentiate tumor from scar. All patients presenting increased uptake of fludeoxyglucose F 18 by the mass were proved by histologic studies to suffer from recurrent tumor. Six of seven patients with low fludeoxyglucose uptake had nonmalignant lesions. Using immunoscintigraphy in 14 patients with elevated carcinoembryonic antigen levels, only four of ten recurrences could be identified by increased antibody accumulation in the mass. On the other hand, two of four benign lesions were interpreted as being recurrent tumor because of high uptake. Therefore, only positron emission tomography seems to be a useful diagnostic tool in the differentiation of recurrent rectal cancer and scar by providing information about the metabolic activity of a mass.

(*Arch Surg* 1989;124:197-200)

After curative surgical resection of rectal cancer, local tumor recurrence has been observed in 30% of patients.[1] When patients present with clinical signs of recurrence during follow-up, computed tomography (CT) of the pelvis is performed. In the case of a suspicious pelvic soft-tissue mass, however, differentiation between recurrent tumor and scar often is a problem. Needle biopsy guided by CT is an invasive procedure that cannot be used as a standard procedure and is reliable only in the case of a positive finding. To solve the problem of differentiation between scar and cancer, we investigated the feasibility and utility of two new diagnostic tools: positron emission tomography (PET) (for measurement of metabolism in the suspicious mass) and immunoscintigraphy. It has been demonstrated that neoplastic tissue has an augmented metabolic rate with increased glycolysis and lactate production that result in a high glucose consumption rate.[2,3] After the intravenous injection of fludeoxyglucose F 18, increased accumulation of this positron emitter in neoplastic tissue can be measured by PET.[4,5] Since the time monoclonal antibodies were developed, there have been efforts to use them for diagnosis and therapy.[6-8] A high percentage of colorectal tumors produce carcinoembryonic antigen (CEA) and carboanhydrate antigen 19-9 (Ca 19-9) and serial CEA/Ca 19-9 measurements have been used in postoperative follow-up studies.[9-11] In the case of an unexplained increase in CEA/Ca 19-9 levels, immunoscintigraphy has been performed to localize the tumor.[12] Therefore, we performed immunoscintigraphy with radioactive-labeled CEA/Ca 19-9 antibodies in the patients who had a suspicious pelvic mass and elevated CEA/Ca 19-9 levels. We investigated the hypothesis that antibody accumulation in the pelvic mass might give additional information and help to differentiate scar and cancerous tissue.

PATIENTS AND METHODS

After curative resection of rectal cancer, 18 patients showed clinical signs of recurrent disease during follow-up. Eleven of the patients had undergone anterior resection and seven had undergone abdominoperineal extirpation of the rectal tumor. Histologic staging of the primary tumor disclosed a pT2 tumor in four cases, a pT3 tumor in ten cases, and a pT4 tumor in four cases. The median disease-free interval was 15 months. In all patients a pelvic mass could be demonstrated by CT (Fig 1, top). All patients underwent PET to evaluate the potential of metabolic measurements for differentiating benign from malignant lesions. All patients were required to have a lesion diameter exceeding 1.5 cm to be included in the study (Table). After identification and marking of the CT section showing the greatest tumor diameter, PET was performed using a whole-body PET scanner (Scanditronix Co, Uppsala, Sweden, PC 2048-7 WB). The fludeoxyglucose F 18 (FDG), with an activity ranging from 115 to 440 megabecquerels, was injected intravenously and sequential images were acquired at five-minute intervals for a total of one hour. The PET cross-sectional images were compared with the corresponding CT images to permit positive identification of the lesion. For quantification of FDG uptake, a region-of-interest technique was used and time-activity curves were calculated from each series. Quantitative uptake of the radionuclide was measured in the suspicious mass as well as in the region of the gluteal muscles, which were

Fig 1.—Top, Pelvic mass (arrow) representing recurrent rectal cancer demonstrated in computed tomographic cross section. Bottom, Representative positron emission tomographic image (57.5 minutes after injection of fludeoxyglucose F 18) of same patient with high fludeoxyglucose F 18 accumulation in pelvic mass (arrow), indicating recurrent rectal cancer.

used as a normal soft-tissue reference. Tracer uptake was expressed as a differential absorption ratio (DAR), as follows: tissue concentration (nanocuries/gram)/[injected dose (nanocuries)/body weight (grams)]. Fourteen of the 18 patients had elevated CEA (>5 ng/mL) or Ca 19-9 (>35 U/L) levels. In these patients, immunoscintigraphy using a cocktail of J-131–labeled $F(ab')_2$-fragments of monoclonal antibodies specific against CEA and Ca 19-9 (IMA CIS Firma CIS, Dreieich, Federal Republic of Germany) was performed. After intravenous administration of the labeled antibodies with a maximal dose of 72 megabecquerels, planar scintigraphic images in the anterior, posterior, and right lateral positions with as many as 100 kilocounts for each image were obtained on days 1, 3, 5, and 7 using a gamma scintillation camera (Ohio Nuclear, Sigma 410, Wiesbaden, Federal Republic of Germany; parallel hole collimator). Tracer accumulation in the pelvic area was assessed and tumor recurrence was assumed in the case of increased tracer uptake in the suspicious pelvic mass. For confirmation of the diagnosis made by PET and immunoscintigraphy, histologic studies of resected tumor specimens or serial biopsy specimens were used. In addition, the patient's clinical course and the change in the size of the mass that was judged to be benign were observed for at least four months using CT.

RESULTS

Increased uptake of FDG corresponding to an increased metabolic rate in the suspicious pelvic mass, as compared with reference soft tissue, could be seen by PET in 11 of the 18 patients (Fig 1, bottom). All of these patients were

Activity of Fludeoxyglucose F 18

Tissue	Mean (±SD) DAR, Time After Infusion*			
	7.5 min	17.5 min	37.5 min	57.5 min
Recurrent cancer (n=11)	2.35±0.4	2.05±0.5	1.90±0.6	2.05±0.7
Scar (n=6)	1.1±0.2	1.0±0.3	0.8±0.3	0.75±0.3
Soft tissue (n=18)	0.75±0.3	0.75±0.3	0.7±0.3	0.75±0.3

*DAR indicates differential absorption ratio.

shown by histologic studies to have recurrent rectal cancer. In these patients a rapid FDG uptake could be measured in the pelvic mass, followed by a slight decrease of the DAR up to 40 minutes after injection (Fig 2). At the end of the PET measurement (57.5 minutes after FDG injection), the tracer concentration was nearly three times as high as in normal soft tissue (Fig 3), with a FDG tumor-to-soft tissue ratio of 2.7. Therefore, the tumor region could clearly be discriminated from normal soft tissue. Six of the 14 patients with elevated CEA/Ca 19-9 levels manifested increased labeled antibody uptake in the pelvic mass. However, in only four of these six patients could a recurrence of rectal cancer be proved. Eight of the 14 patients with elevated tumor marker levels did not show any substantial antibody accumulation within the area of the pelvic mass that would falsely indicate a benign lesion. Histologic findings disclosed scar tissue only in two of these eight patients. Using PET, normal FDG uptake in the pelvic mass could be measured in seven of the 18 patients. In these patients a moderate increase in the FDG concentration up to 15 minutes after injection could be observed in the lesion by PET. This was followed by a continuous decrease in DAR values (Fig 3). Mean DAR values at the end of the measurement were identical for both nonmalignant scar tissue and normal reference soft tissue, with a scar tissue–to–soft tissue ratio of 1.0. Histologic examination could verify the presence of scar tissue in six of the seven patients with normal FDG uptake. One of these seven patients showed a recurrent malignant tumor. Therefore, there only was one false-negative result in 18 cases, indicating that a clear discrimination between cancer and soft tissue, as well as scar tissue, could be obtained by measurement of the metabolic rate using PET. Differentiation between scar tissue and cancer was best 57.5 minutes after injection of FDG. Sensitivity in differentiation was 92%, with a specificity of 100%, resulting in a positive predictive value of 100% and a negative predictive value of 86%. Immunoscintigraphy, however, only detected four of ten recurrences and two of four benign lesions. These four patients with elevated CEA/Ca 19-9 levels were later found to have liver metastases from the rectal cancer. In six cases false-negative results and in two cases false-positive results were seen. Sensitivity, therefore, was only 40% and specificity was 50%, resulting in a low negative predictive value of 25% and a positive predictive value of 67%.

COMMENT

Measurement by PET of FDG metabolism in malignant tumors has already been described earlier: an increased FDG uptake has been seen in gliomas. A correlation between FDG uptake and differentiation of the tumor has even been observed.[13] In pulmonary neoplasms there was a substantially increased FDG accumulation compared with normal pulmonary tissue.[14] In the present

Fig 2.—Mean time-activity curve and SD for colorectal tumor, scar tissue, and reference soft tissue after intravenous injection of fludeoxyglucose F 18. DAR indicates differential absorption ratio.

Fig 3.—Study design. CEA indicates carcinoembryonic antigen.

study, for the first time we could measure metabolic activity of pelvic masses using PET in the follow-up of patients with rectal cancer. We could show that FDG uptake in recurrent tumor was nearly three times as high as in normal soft tissue. This correlates with investigations in which an increased glycolysis in cancer tissue was found.[13,14] This could be explained by increased glucose transport through the cell membrane[3] or an enhanced capacity for glycolysis because of increased activity of the glycolytic enzymes. Scar tissue disclosed a metabolic activity similar to that of normal soft tissue. Cancerous tissue, therefore, could be clearly discriminated by PET from normal soft tissue, as well as from cancerous tissue. Time-activity curves show that only a few measurements are necessary to make this discrimination. The disappointing results with immunoscintigraphy in differentiating between scar and cancerous tissue in the case of a suspicious pelvic mass are contrary to the reliability of this method as described by other authors.[3,15,16] Because the same methodologic approach was used in our studies, the different results might be explained by the fact that other authors mostly compared CT, sonography, and other diagnostic methods with immunoscintigraphy, but not with histologic findings. In our experience, immunoscintigraphy cannot give additional information beyond that provided by conventional diagnostic tools in the case of a suspicious pelvic mass. Positron emission tomography, however, seems to be a useful adjunctive procedure that provides information about the metabolic activity of a mass. By this method, selection of patients for invasive diagnosis and therapy could be improved.

Discussion

Q Was the immunoscintigraphy performed using SPECT or were only the planar images used?

A In the beginning of our study we used planar scintigraphy. Now we use SPECT, but in our experience there really is no difference between the methods. I think the main problem is specificity and the distribution of the antibody.

Q In the immunologic studies, did you test whether the antigen against which the antibody is prepared was present in the individual patients who were tested?

A We investigated all of the operative specimens according to CEA staining or Ca 19-9 staining by an immunologic method. In all 14 of these patients, the immunologic staining was positive, so it should be detected by the immunoscintigraphy.

Q This seems to be a question of delivery of the antibody, rather than a lack of antigen.

A I think it is not a problem of delivery only but is an effect of binding and specificity of the antibody we used.

Q We studied recurrence in patients with rising CEA levels whose CT scans were normal. Sensitivity in the identification of lesions was 85% in our study. Perhaps this sensitivity was different because our patients had relatively low CEA levels at the time of detection and perhaps your patients had much higher levels and larger lesions.

A No, all of these patients had CEA levels no higher than 50 ng/mL. Only in combination with liver metastases is the CEA level increased. There are many reports in the literature on the very high sensitivity and specificity of different immunoscintigraphy methods. I think the main problem in most of these studies is that they have investigated the sensitivity and specificity only in relation to conventional diagnostic findings. There are not many studies in which intraoperative findings and the histologic examination of the specimen were correlated with preoperative metabolic studies. This is the main reason that the results are different.

Meeting the surgical challenge: hernia repair.

This remarkable surgical patch, capable of tissue incorporation and possessing both strength and superior handling, is used in even the most demanding soft tissue repairs.

Clinical experience shows that the GORE-TEX™ Soft Tissue Patch provides dependable reinforcement and suture retention, low levels of complications, and conforms easily to the contours of the natural tissue.

And yet, the high, balanced strength of the Soft Tissue Patch does not sacrifice the softness of the material. The result is less tissue irritation and greater comfort for the patient postoperatively.

Also, it is highly versatile. It is widely used in clinical applications ranging from hernia repairs, including large abdominal wall defects, to prolapse, banding and reconstruction of tissue deficiencies.

Tissue ingrowth is encouraged by the microporous structure of the GORE-TEX Soft Tissue Patch, unlike other prostheses that can become encapsulated by fibrous scar tissue. Recent clinical publications and experience support greater tissue acceptance and a significantly lower incidence of visceral adhesions in the experimental model.

Packaged sterile, the GORE-TEX Soft Tissue Patch comes in both 1.0mm and 2.0mm thicknesses and can be resterilized.

It provides unmatched performance: superior handling, incorporation, resistance to adhesion formation and treatability in the presence of infection.

For more information, use the coupon or call, toll free, 800/638-4804.

Prognostic Significance of Cellular Immunity to Autologous Breast Carcinoma and Glycoprotein 55

Maurice M. Black, MD; Reinhard E. Zachrau, MD; Roy H. Ashikari, MD; Benjamin F. Hankey, ScD

• Using a skin window (SW) procedure, we evaluated postoperative cell-mediated immunity (CMI) to autologous breast cancer with reference to its prognostic significance, the nature of the immunogen, and the therapeutic implications. It appears that SW reactivity to autologous breast cancer is prognostically favorable per se and is independent of the prognostic significance of the nuclear grade of the cancer cells; SW reactivity to autologous breast cancer reflects CMI to a determinant(s) that is expressed by glycoprotein 55, the principal envelope glycoprotein of the RIII-murine mammary tumor virus; the glycoprotein 55–like CMI determinant(s) is more regularly expressed by preinvasive than by invasive breast cancers; tumor antigenicity and host reactivity may vary independently; and postoperative monitoring of CMI to autologous breast cancer is prognostically and therapeutically important.

(*Arch Surg* 1989;124:202-206)

Numerous studies have demonstrated that the biological behavior of breast cancer reflects interactions between the aggressive potential of the cancer and tumor-retarding influences of the host. The aggressive potential is inversely correlated with the microscopically demonstrable differentiation of the cancer cell nuclei (nuclear grade [NG]).[1,2] More recently, automated cytophotometry has been utilized to provide numerical representations of the microscopically demonstrable variations in the NG.[3] The salient point is that variations in the NG are associated with highly significant differences in survival. However, the survival characteristics are also influenced by immunological host responses to the tumor. Such prognostically significant responses are microscopically evident in the primary cancer and in the regional lymph nodes as lymphoreticuloendothelial cellular reactions that are consistent with cell-mediated immunity (CMI).[2,4,5] Manifestations of such CMI are also demonstrable by means of in vitro[6-8] and in vivo[9-11] measurements. Each of these indexes demonstrates that immunogenicity develops during the preinvasive phase of breast cancer and that immunologically mediated tumor retardation depends on both, the retention of the specific antigenicity of the cancer cells and the specific CMI of the host.[12,13]

We now report on expanded observations on the prognostic significance of specific immunity against NG-characterized autologous breast cancer, as evaluated in vivo by the skin window (SW) procedure. We shall demonstrate that the prognostically favorable SW reactivity in patients with breast cancer is directed against a CMI determinant(s) that is similar to a determinant(s) expressed by glycoprotein 55 (gp55), the principal envelope glycoprotein of the RIII-murine mammary tumor virus, and that is more regularly expressed by preinvasive than by invasive breast cancers.

PATIENTS AND METHODS

Our study population included those patients with operable breast cancer characterized in our previous report on SW reactivity to autologous breast cancer.[11] In addition to expanded clinical follow-up data, this report includes results on the SW responses of these patients to gp55. We also report on the responses to gp55 in a series of patients with breast cancer who were not tested against autologous breast cancer. All SW tests were performed on patients who had no evidence of metastases or second primary cancers. Informed consent, as approved by the New York Medical College (Valhalla) Committee for Protection of Human Subjects, was obtained from all study participants.

The gp55 was isolated from virus derived from milk of RIII-strain mice. The isolation procedure has been described in a previous publication.[14] For SW testing, 2 μg of gp55 was applied to the center of 25-mm-diameter round glass coverslips. After air drying, the coverslips were immersed for 15 minutes in a 1:1 mixture of ether and 95% ethanol, air dried again, and stored at −20°C until use.

The SW test procedure involved the application of a target-containing (gp55 or autologous tumor) coverslip to an abraded area of skin for approximately 30 hours. After removal, the coverslip was stained with Wright's stain and evaluated as to type and extent of the cellular response. The various patterns of responses and their classification have been defined previously.[9,11] In essence, the stained coverslips were examined microscopically for focal aggregations of mononuclear cells of the histiocytic or lymphoblastoid type, having nonvacuolated cytoplasm that is typically basophilic. The histocytic-type aggregates may be monolayered or multilayered. In the lymphoblastoid-type aggregates, the cells may be spherical or hand-mirror–shaped, and multinucle-

ated Langhans' giant cells may be present. Less commonly, the cellular response is in the form of aggregates of elongated and multipolar histiocytic cells (stellate type) or of lymphoblastoid cells with associated neutrophilic, eosinophilic, and basophilic polymorphonuclear leukocytes. Basophils and/or eosinophils may also be scattered among the other types of responses. None of these response patterns is found when either blank coverslips or coverslips with normotypic breast tissue are applied to patients with breast cancer or to control subjects.

Numerical values were assigned in relation to the size of aggregates of any of the above described types, namely, 1 for less than 25%, 2 for 25%, 3 for 50% to 75%, and 4 for more than 75% occupation of a low-power (×100) microscopic field. The collective designation "positive" is given to any of the described response patterns when the aggregates occupy 50% or more of a low-power field (SW response of 3 or higher). Skin window responses with aggregates occupying 25% to less than 50% of a low-power field are designated as "borderline positive." The designation "negative" is given to SW responses with aggregates occupying less than 25% of a low-power field (SW response of 1), those with larger aggregates showing prominent cytonecrosis, and those without distinct types of aggregates.

The data were evaluated by one of us (B.F.H.), utilizing the statistical methods cited in our prior report.[11]

RESULTS

Skin Window Reactivity Against Autologous In Situ and Invasive Breast Cancer

The results of the SW tests against autologous stage 0 in situ breast cancer and against invasive breast cancer during the one- to 24-month postoperative interval are listed in Table 1. As judged by the total number of tests, positive (≥3) responses were proportionately more frequent among patients with in situ (46%) than those with invasive (19%) breast cancer ($P<.0001$). A similar difference in SW reactivity between patients with in situ and those with invasive breast cancer was found in terms of the maximal response per patient during the one- to 24-month postoperative interval, namely, 60% vs 31% ($P<.001$). Table 1 also lists the distribution of SW responses of those patients with invasive breast cancer who developed systemic metastases less than 30 or 30 months or more after SW tests that had been performed at diverse postoperative intervals. Positive (≥3) SW responses against autologous invasive breast cancer were uncommon (5%) among patients who developed metastases less than 30 months after testing and significantly less frequent than among patients who developed metastases 30 months or more after testing (21%) ($P<.0001$).

Skin Window Reactivity Against gp55 Among Patients With In Situ and Invasive Breast Cancer

As shown in Table 2, the relative frequency of positive (≥3) SW responses against gp55, one to 24 months postoperatively, was greater among patients with in situ than patients with invasive breast cancer. This difference is statistically significant for the total number of positive tests. Evaluation by maximal response per patient during this interval shows the same trend, but that difference is not statistically significant.

Comparison of the observations (Tables 1 and 2) reveals that, among patients with invasive breast cancer, positive reactivity was more frequently found against gp55 than against the autologous carcinoma, namely, 30% vs 19% ($P<.0005$), by total number of tests, and 52% vs 31% ($P=.002$), by maximal response per patient during the one- to 24-month postoperative interval. The proportion of positive SW responses to gp55 was also significantly greater than that to autologous carcinoma among patients with invasive breast cancer who subsequently developed

systemic metastases. This was particularly evident among patients who developed metastases more than 30 months after SW testing (26% vs 5%, $P<.0005$), but to a lesser extent also among those who developed metastases 30 months or more after testing (34% vs 21%, $P<.05$). All of these differences in reactivity against autologous breast cancer and gp55 indicated the need to examine the reactivity against both targets by simultaneous testing in individual patients.

Simultaneous SW Reactivity Against Autologous Breast Cancer and gp55

Quantitative Features.—As shown in Table 3, among both patients with in situ and those with invasive breast cancer, failure to respond to gp55 was characteristically associated with failure to respond to the autologous carcinoma in simultaneous tests. This was observed in tests performed over a wide range of postoperative intervals, ie, from one month to more than ten years. However, the proportions of simultaneous tests that were negative to both gp55 and autologous carcinoma differed between the in situ and the invasive breast cancer series, ie, 31% vs 54% ($P<.0005$).

Patients with in situ and patients with invasive breast cancers differed also in regard to the relative frequency of simultaneous reactivity against gp55 and autologous carcinoma: in the in situ cancer patient series, positive reactivity against gp55 was associated with positive reactivity against autologous cancer in 78% of the tests, compared with 52% in the invasive cancer patient series ($P<.005$). It should also be noted that simultaneous positive reactivity against both gp55 and autologous cancer was found in 37% of the in situ cancer patient series in contrast to only 14% of the invasive cancer patient series ($P<.0001$).

These observations suggest that positive SW reactivity against autologous breast cancer reflects host reactivity against a CMI determinant(s) that is expressed by gp55, *and* the presence of such a gp55-like CMI determinant(s) in the breast cancer cells. It further appears that host reactivity and breast cancer antigenicity may vary independently.

Qualitative Features.—As mentioned above, the SW responses to autologous breast cancer may show qualitative as well as quantitative variations among different patients and in the same patient at different times. Analogous variations in SW responses have been observed in tests against gp55. It was, therefore, of interest to examine the qualitative characteristics of *simultaneous* SW responses to gp55 and autologous breast cancer in those instances in which the SW reactivity against gp55 was positive (≥3) at any postoperative interval.

As shown in Table 4, the qualitative SW characteristics were divided into the following three groups: lymphoblastoid, histiocytic, and other types. The simultaneous responses to the autologous carcinoma were grouped according to the quantitative features, ie, 3 or more (positive), 2 (borderline positive), and 1 (negative). In addition, positive (≥3) responses to the autologous cancer were subdivided into those with the same and those with a different type of response. The in situ breast cancer patient series revealed a particularly striking similarity between the simultaneous SW responses to gp55 and autologous cancer, ie, 71% were both qualitatively and quantitatively similar. This degree of similarity was significantly ($P<.005$) greater than that found in the invasive breast cancer patient series (43%).

Considered in toto, the data of Tables 3 and 4 support the view that immunogenic human breast cancers express a CMI determinant(s) that is similar to a CMI determinant(s) expressed by RIII-gp55. It further appears that such antigenicity regularly accompanies the preinvasive phase of mammary carcinogenesis but is less regularly expressed by invasive breast cancers.

Prognostic Significance of SW Reactivity Against Autologous Invasive Breast Cancer and gp55

The prognostic influence of SW reactivity against autologous breast cancer, per se and in relation to the NG of the

Fig 1.—Proportion of patients with invasive breast cancer free of metastases at increasing postoperative intervals, in relation to maximal skin window (SW) reactivity against autologous carcinoma, one to 24 months postoperatively. Positive (SW response, ≥2) includes 129 patients; negative, (SW response, <2) 150 patients.

Fig 2.—Proportion of patients with invasive breast cancer free of metastases at increasing postoperative intervals, in relation to nuclear grade (NG) and maximal skin window (SW) reactivity against autologous carcinoma, one to 24 months postoperatively. Patient numbers by category were as follows: NG I: SW positive, 43, and SW negative, 63; NG II: SW positive, 54, and SW negative, 62; NG III: SW positive, 32, and SW negative, 25.

cancer, is depicted in Figs 1 and 2, respectively. The Kaplan-Meier survival curves are consistent with those reported previously[11] and demonstrate the prognostic significance of SW reactivity. Figure 2 also illustrates the independent prognostic significance of the NG. The prognostic significance of the differences between the SW-positive and SW-negative Kaplan-Meier survival curves was evaluated by adjusted and unadjusted Mantel-Haenszel χ^2 tests.[15] In addition, the Cox proportional hazards model was used to analyze the joint effects on prognosis of clinical and pathologic variables in conjunction with the SW test status.[16] These procedures demonstrate the prognostic significance of SW reactivity *after* adjustment for the variables patient age, lymph node status, and NG of the cancer.

With respect to the prognostic significance of SW reactivity against gp55, it is noteworthy that 15 of our patients with negative SW responses to autologous invasive breast cancer, one to 24 months postoperatively, showed positive (≥3) reactivity in simultaneous tests against gp55 on at least one occasion. Eleven of these patients, however, had shown positive SW reactivity against autologous breast cancer at least once before or after the discrepant responses. Only one of these 11 patients so far has developed systemic metastases that occurred 76 months postoperatively. Ten of these 11 patients are free of recurrent disease at 24, 28, and 61 to 80 months postoperatively. The remaining four patients were consistently nonreactive against their autologous cancer in four to eight tests, despite one or more positive SW responses to gp55 in simultaneous tests. In contrast to the aforementioned 11 patients, all four of the latter group developed systemic metastases less than 36 months postoperatively. These findings indicate that breast cancer antigenicity and specific host CMI may vary independently and that the prognostic significance of SW reactivity against gp55 depends on the expression of the gp55-like CMI determinant(s) by the cancer cells.

COMMENT

Our study provides further evidence of the prognostic significance of SW reactivity against autologous breast cancer, as a single variable and in association with the NG of the cancer cells. Since the prognostic significance of CMI to autologous breast cancer is maintained over a wide range of postoperative intervals, agents or procedures that are capable of inducing a negative-to-positive change in SW reactivity against autologous breast cancer should reduce the development and/or progression of metastatic disease over a broad range of postoperative intervals. It is important that studies of putative immunotherapeutic agents include measurements of specific reactivity against autologous cancer before and after treatment.[10] The failure to perform such measurements makes it difficult, if not impossible, to determine whether the treatment in question has immunostimulatory capabilities, let alone therapeutic benefits.

Among patients with in situ breast cancers, there is a striking similarity in the responses to gp55 and autologous cancer, both qualitatively and quantitatively. Thus, it appears that a gp55-like CMI determinant(s) is regularly expressed during the preinvasive phase of breast cancer. A significant minority may cease to express this determinant(s) during the invasive phase of the disease. This conclusion follows from our microscopic findings[12] as well

as from in vitro[17,18] and in vivo[10] measurements. Of particular importance are our current observations that indicate that an unfavorable prognosis is associated with those breast cancers that seem to lack the gp55-like CMI determinant(s). An awareness of the existence of such breast cancers is also important in studies of putative immunotherapeutic procedures. Thus, agents that might be able to stimulate specific immunity, ie, convert negative into positive responses to gp55, would nevertheless be incapable of exerting a tumor-retarding effect on the antigen-deficient autologous cancer cells.

Mesa-Tejada et al[19] have reported that human breast cancer tissues may express an antigenic component that acts as a target for xenogenic anti-gp55 antibodies. Such antibodies, however, do not preferentially react with in situ compared with invasive human breast cancer. Moreover, there is some evidence that the antibody-targeted antigens are more commonly associated with breast cancers with an unfavorable prognosis[20] and with breast cancers of patients with a family history of breast cancer.[21] Such relationships are not evident with regard to the gp55-like CMI determinant(s) of human breast cancer nor with regard to SW reactivity against gp55. Also, patients with breast cancer rarely manifest circulating antibodies to gp55[22] or to autologous breast cancer. These differences in the observations on serological and CMI responses to breast cancer emphasize the importance of distinguishing between the two types of immunological reactivity in patients with breast cancer.

The authors thank Arnold S. Dion, PhD, Center for Molecular Medicine and Immunology, Newark, NJ, for the isolation of gp55 from RIII-murine mammary tumor virus.

Discussion

Q Have you taken patients with some of the precursor lesions, such as carcinoma in situ, and atypical hyperplasias to see if they react?

A Well, it depends on your definition. Yes, when I said in situ to preinvasive lesion, that includes lesions that I call precancerous mastopathy, a lesser degree of atypia than overt in situ carcinoma. They are immunogenic in a high proportion of cases.

Q Do you think that late-stage lesions go through the same early reactivity or do you think that these tumors are predestined and bypass this early reactivity? Also, do you have any kind of evidence to discuss that biology?

A In our invasive group there is a wide range of individuals whose disease is merely considered to be operable. But as I showed you, even if you consider those patients who are known to have developed metastases, you have this same relationship. The behavior will be a function not of cure but of survival free of clinically evident metastases. I differentiate metastases from local recurrence; local recurrence is a different bird entirely. You can always measure tumor immunity, host immunity, and tumor antigenicity, and the behavior will always be the same and predictable at any stage, at any interval postoperatively.

Q Do you feel that the early immune response stimulates a tumor when it progresses, and can it actually make a contribution to tumor progression?

A No, it is quite the reverse. If you have immunity to the tumor in terms of a definite response to the tumor, by leukocyte migration test, or by any other immunological procedure you wish, it is always associated with a favorable prognosis.

Q Have you had a chance to look at this with flow cytometry to see if you are possibly duplicating the same thing? Did Fig 1 show anything that you could relate to estrogen receptors?

A I introduced nuclear differentiation in 1950, so it has been here a little longer than flow cytometry. Flow cytometric measurements correlate well with NG determinations.[3] Regarding estrogen receptors, I really think that that is after the fact. Patients who have estrogen receptor positivity tend to have well-differentiated nuclei and that is the basis of its prognostic significance,[3] but you do not have to take that into account at all. In fact, it is immaterial after you have taken care of the NG. I think that the NG is a very powerful measurement, and I must emphasize that NG and histological grade are not the same thing. They may sometimes be, but they may be decidedly different. If you rely on histological grade only, you get the most bizarre types of interpretation.

A unique antibiotic

- ☐ Extensive clinical experience
- ☐ Comprehensive *Bacteroides fragilis* group coverage*
- ☐ Consistent activity** (virtually unchanged over time) against *Bacteroides fragilis*
- ☐ No MTT side chain

MEFOXIN is indicated for the treatment of intraabdominal, gynecological, lower respiratory tract, and skin and skin-structure infections due to designated susceptible organisms including members of the *Bacteroides fragilis* group. (See Brief Summary for complete listing of indications.)

MEFOXIN is contraindicated in patients who have shown hypersensitivity to cefoxitin and the cephalosporin group of antibiotics. Before therapy with MEFOXIN is instituted, careful inquiry should be made to determine whether the patient has had previous hypersensitivity reactions to cefoxitin, cephalosporins, penicillins, or other drugs. This product should be given with caution to penicillin-sensitive patients.

Pseudomembranous colitis, from mild to life-threatening in severity, has been reported with virtually all antibiotics (including cephalosporins); therefore, it is important to consider its diagnosis when diarrhea develops in association with antibiotic use.

MSD
MERCK SHARP & DOHME

It's got to be Mefoxin® IV/IM

(Cefoxitin Sodium | MSD)

Indications and Usage: *Treatment*—Serious infections caused by susceptible strains of the designated microorganisms in the following diseases:
LOWER RESPIRATORY TRACT INFECTIONS, including pneumonia and lung abscess, caused by *Streptococcus pneumoniae*, other streptococci (excluding enterococci, e.g., *Strep. faecalis*), *Staphylococcus aureus* (penicillinase and non-penicillinase producing), *Escherichia coli*, *Klebsiella* species, *Hemophilus influenzae*, and *Bacteroides* species.
GENITOURINARY INFECTIONS. Urinary tract infections caused by *E. coli*, *Klebsiella* species, *Proteus mirabilis*, indole-positive *Proteus* (which include the organisms now called *Morganella morganii* and *Proteus vulgaris*), and *Providencia* species (including *Providencia rettgeri*). Uncomplicated gonorrhea due to *Neisseria gonorrhoeae* (penicillinase and non-penicillinase producing).
INTRA-ABDOMINAL INFECTIONS, including peritonitis and intra-abdominal abscess, caused by *E. coli*, *Klebsiella* species, *Bacteroides* species including the *B. fragilis* group,* and *Clostridium* species.
GYNECOLOGICAL INFECTIONS, including endometritis, pelvic cellulitis, and pelvic inflammatory disease, caused by *E. coli*, *N. gonorrhoeae* (penicillinase and non-penicillinase producing), *Bacteroides* species including the *B. fragilis* group,* *Clostridium* species, *Peptococcus* species, *Peptostreptococcus* species, and group B streptococci.
SEPTICEMIA caused by *Strep. pneumoniae*, *Staph. aureus* (penicillinase and non-penicillinase producing), *E. coli*, *Klebsiella* species, and *Bacteroides* species including the *B. fragilis* group.*
BONE AND JOINT INFECTIONS caused by *Staph. aureus* (penicillinase and non-penicillinase producing).
SKIN AND SKIN STRUCTURE INFECTIONS caused by *Staph. aureus* (penicillinase and non-penicillinase producing), *Staph. epidermidis*, streptococci (excluding enterococci, e.g., *Strep. faecalis*), *E. coli*, *P. mirabilis*, *Klebsiella* species, *Bacteroides* species including the *B. fragilis* group,* *Clostridium* species, *Peptococcus* species, and *Peptostreptococcus* species.
Although appropriate culture and susceptibility studies should be performed, therapy may be started while awaiting these results. Cefoxitin is not active *in vitro* against most strains of *Pseudomonas aeruginosa* and enterococci (e.g., *Strep. faecalis*) and many strains of *Enterobacter cloacae*. Methicillin-resistant staphylococci are almost uniformly resistant to cefoxitin.
Prevention—Prophylactic use in surgical procedures (e.g., hysterectomy, gastrointestinal surgery, cesarean section, transurethral prostatectomy) classified as contaminated or potentially contaminated or in patients in whom subsequent infection at the operative site would present a serious risk, e.g., prosthetic arthroplasty.
MEFOXIN® (Cefoxitin Sodium, MSD) usually should be given ½ to 1 hour before surgery and should usually be stopped within 24 hours since continuing administration of any antibiotic increases the possibility of adverse reactions but, in the majority of surgical procedures, does not reduce the incidence of subsequent infection. However, in patients undergoing prosthetic arthroplasty, it is recommended that MEFOXIN be continued for 72 hours after the surgical procedure. If there are signs of infection, specimens for culture should be obtained for identification of the causative organism so appropriate treatment may be instituted.

Contraindications: Previous hypersensitivity to cefoxitin and the cephalosporin group of antibiotics.

Warnings: BEFORE THERAPY IS INSTITUTED, CAREFUL INQUIRY SHOULD BE MADE TO DETERMINE PREVIOUS HYPERSENSITIVITY REACTIONS TO CEFOXITIN, CEPHALOSPORINS, PENICILLINS, OR OTHER DRUGS. GIVE WITH CAUTION TO PENICILLIN-SENSITIVE PATIENTS. ANTIBIOTICS SHOULD BE ADMINISTERED WITH CAUTION TO ANY PATIENT WHO HAS DEMONSTRATED SOME FORM OF ALLERGY, PARTICULARLY TO DRUGS. IF AN ALLERGIC REACTION TO CEFOXITIN OCCURS, DISCONTINUE THE DRUG. SERIOUS HYPERSENSITIVITY REACTIONS MAY REQUIRE EPINEPHRINE AND OTHER EMERGENCY MEASURES.
Pseudomembranous colitis, from mild to life-threatening in severity, has been reported with virtually all antibiotics (including cephalosporins); therefore, it is important to consider its diagnosis when diarrhea develops in association with antibiotic use. Broad-spectrum antibiotics alter normal flora of colon and may permit overgrowth of clostridia; a toxin produced by *Clostridium difficile* is a primary cause of antibiotic-associated colitis. Mild cases may respond to drug discontinuance alone; in more severe cases, management may include sigmoidoscopy, appropriate bacteriological studies, fluid, electrolyte and protein supplementation, and use of a drug such as oral vancomycin; isolation of the patient may be advisable. Other causes of colitis should also be considered.

Precautions: *General*—Total daily dose should be reduced in patients with reduced urinary output due to renal insufficiency because high and prolonged serum antibiotic concentrations can occur from usual doses. Prescribe with caution in patients with a history of gastrointestinal disease, particularly colitis. Prolonged use may result in overgrowth of nonsusceptible organisms; repeated evaluation of the patient's condition is essential. If superinfection occurs, take appropriate measures.
Drug Interactions—Increased nephrotoxicity has been reported following concomitant administration of cephalosporins and aminoglycoside antibiotics.
Drug/Laboratory Test Interactions—High concentrations (>100 mcg/mL) may interfere with measurement of serum and urine creatinine levels by the Jaffé reaction and produce false increases of modest degree in creatinine levels reported; serum samples should not be analyzed for creatinine if withdrawn within 2 hours of cefoxitin administration. High concentrations may interfere with measurement of urinary 17-hydroxy-corticosteroids by the Porter-Silber reaction and produce false increases of modest degree in levels reported. A false-positive reaction for glucose in urine has been observed with CLINITEST** reagent tablets.
Carcinogenesis, Mutagenesis, Fertility Impairment—No long-term animal study has been performed on carcinogenic or mutagenic potential. Rat studies at approximately three times maximum recommended human dosage revealed no effects on fertility or mating ability.
Pregnancy Category B—Reproduction studies in rats and mice did not reveal teratogenic or fetal toxic effects, although fetal weights were slightly decreased. In rabbits, cefoxitin was associated with a high incidence of abortion and maternal death, neither considered teratogenic. There are, however, no adequate and well-controlled studies in pregnant women. Because animal reproduction studies are not always predictive of human response, this drug should be used during pregnancy only if clearly needed.
Nursing Mothers—Excreted in human milk: Exercise caution.
Pediatric Use—Safety and efficacy in infants from birth to three months have not yet been established. In children three months and older, higher doses have been associated with increased incidence of eosinophilia and elevated SGOT.

Adverse Reactions: The most common adverse reactions have been local reactions following intravenous or intramuscular injection. Other adverse reactions have been encountered infrequently. *Local Reactions*—Thrombophlebitis with intravenous administration; pain, induration, and tenderness after intramuscular injections. *Allergic Reactions*—Rash (including exfoliative dermatitis), pruritus, eosinophilia, fever, and other allergic reactions including anaphylaxis. *Cardiovascular*—Hypotension.
Gastrointestinal—Diarrhea, including documented pseudomembranous colitis during or after treatment, and, rarely, nausea and vomiting. *Blood*—Eosinophilia, leukopenia including granulocytopenia, neutropenia, anemia, including hemolytic anemia, thrombocytopenia, and bone marrow depression. A positive direct Coombs test may develop in some individuals, especially those with azotemia. *Liver Function*—Transient elevations in SGOT, SGPT, serum LDH, and serum alkaline phosphatase; jaundice. *Renal Function*—Elevations in serum creatinine and/or blood urea nitrogen levels and, rarely, acute renal failure.

Note: In group A beta-hemolytic streptococcal infections, therapy should be maintained for at least 10 days to guard against the risk of rheumatic fever or glomerulonephritis. In staphylococcal and other infections involving a collection of pus, surgical drainage should be carried out where indicated. Intramuscular injections should be well within the body of a relatively large muscle such as the upper outer quadrant of the buttock (i.e., gluteus maximus); aspiration is necessary to avoid inadvertent injection into a blood vessel. The total daily dosage in infants and children should not exceed 12 grams.

How Supplied: Sterile cefoxitin sodium in vials, infusion bottles, and ADD-Vantage®‡ vials containing 1 gram or 2 grams cefoxitin equivalent and in 10-gram bulk bottles.

* *B. fragilis*, *B. distasonis*, *B. ovatus*, *B. thetaiotaomicron*, *B. vulgatus*

Photodynamic Therapy for Cutaneous and Subcutaneous Malignant Neoplasms

James S. McCaughan, Jr, MD; Jerry T. Guy, MD; William Hicks, MD; Leslie Laufman, MD; Thomas A. Nims, MD; John Walker

• Twenty-seven patients with cutaneous and subcutaneous malignant neoplasms were treated with photodynamic therapy. Therapy was administered to 248 areas during a total of 72 separate treatment sessions after patients received a total of 45 injections of sensitizer. Seven patients had basal cell carcinoma, three had squamous cell carcinoma, three had malignant melanoma, one had liposarcoma, and 12 had breast cancers. One patient had Bowen's disease. Treatment was given either by surface radiation or interstitially. One month after treatment, 48 (67%) of the treatment sessions resulted in a complete response (no clinical evidence of tumor), and 19 (26%) resulted in a partial response (>50% reduction in the number or size of tumors). Fifteen patients were examinable 12 months after treatment, and in this group, 31 treatment sessions were evaluated as a complete response one month after therapy, 15 (48%) of which retained this status at one year after treatment. By comparing the ability of different light-delivery instrumentation, it was concluded that the Yellow Springs radiometer (Yellow Springs Instruments, model 65A, Yellow Springs, Ohio) provided the most reliable spot power density readings. Straight-tipped fibers are nonhomogeneous and can result in overtreatment of the central area with necrosis and pain and in undertreatment of the periphery.

(*Arch Surg* 1989;124:211-216)

It has been known since 1924[1] that the presence of endogenous porphyrins causes some tumors to give off a red-orange fluorescence when exposed to ultraviolet light. Subsequent studies in rats showed that systemic injections of hematoporphyrin gave the characteristic red-orange fluorescence in tumors but not in normal tissue.

In 1961, Lipson and Baldes[2] reported using a hematoporphyrin derivative that was prepared by treating hemoglobin with an acetic acid–sulfuric acid solution. The derivative from this process produced a higher degree of fluorescence to the tumors than the original hematoporphyrin.

Original work was aimed at using fluorescence of tumors as a diagnostic technique. In 1968, Gregorie and Horger[3] found a 75% to 85% correlation of fluorescence with positive biopsy specimens of squamous carcinomas and adenocarcinomas in 226 patients who were treated with intravenous hematoporphyrin derivative.

In 1972, Diamond and Granelli[4] reported destruction of experimental tumors by exposing them to white light after systemic injection of hematoporphyrin derivative. Subsequently, Dougherty and his group at Roswell Park Memorial Institute, Buffalo, NY, began their laboratory animal experimentation by using hematoporphyrin derivative and various light systems to administer photodynamic therapy (PDT).

In 1984, Dougherty et al[5] extracted an active mixture from hematoporphyrin derivative called dihematoporphyrin ether, which is given intravenously and disseminates throughout the entire body. Because it begins to clear rapidly from normal cells while remaining in tumor tissue, after several days, the concentration of hematoporphyrin derivative is greater in tumor tissue relative to adjacent normal tissue. As a dye, hematoporphyrin derivative absorbs light at certain wavelengths. Although the greatest absorption occurs in the 405-nm range (blue-green), another absorption peak occurs in the 630-nm (red) range of wavelengths and is preferred for this treatment because it penetrates tissue better. When the light is absorbed, the dye is activated, and singlet oxygen[6] is produced, causing death to tumor tissue. Normal tissue remains relatively unharmed because it no longer contains sufficient dye to cause a reaction at the light doses employed.

Since 1978, numerous investigators have used PDT to treat patients with a variety of tumors by using various light sources, methods of delivery, and dose measurements.[7-17] In 1982, we treated five patients with skin cancers by using projectors (Kodak) and red filters as the light source.[18]

This report details the results of PDT administered during a five-year period to patients with various skin and subcutaneous malignant neoplasms. A tunable dye argon laser system was used for the light source. The report also compares the ability of different light-delivery instrumentation to estimate the light doses delivered and the relationship of power density and temperature.

PATIENTS AND METHODS

All patients had received, refused, or were ineligible for conventional surgery, chemotherapy, or ionizing radiation therapy. All patients were informed of the investigational nature of the treatment. Patients and their relatives watched a slide presentation and received pamphlets from an oncologic nurse specialist who described the technique. The nurse also emphasized the need for patients to avoid direct sunlight exposure for one month after treatment. Patients were further counseled to limit their sunlight exposure during the second posttreatment month.

Twenty-seven patients received a total of 45 injections of sensitizer and underwent a total of 72 separate treatment sessions. Most patients underwent treatment of multiple lesions; in all, a total of 248 cutaneous or subcutaneous areas were treated. Seven patients had basal cell carcinoma, three had squamous cell carcinoma, three had malignant melanoma, one had liposarcoma, and 12 had breast cancers. One patient had Bowen's disease.

The photosensitizer was injected through a running intravenous line of 5% glucose in Ringer's lactate solution as a single bolus. Initially, patients were given 3.0 mg/kg of hematoporphyrin derivative (Photofrin I, Photofrin Medical Inc, Cheektowaga, NY). Later, 2.0 mg/kg of dihematoporphyrin ether (Photofrin II, Photofrin Medical Inc, Cheektowaga, NY, or Johnson & Johnson Products Inc, Raritan, NJ) was used.

Two to six days after injection of the sensitizing agent, the tumor areas were treated with 630 ± 2 nm of light, delivered through 400- or 600-μm quartz fibers. The 630-nm therapeutic light was generated by a 20-W argon laser (Spectra Physics, model

171, Mt View, Calif) that pumped a tunable dye laser (Spectra Physics, model 375), initially circulating rhodamine-B dye without the tuning wedge and later with Kiton Red using a single plate birefrigent filter. The wavelength was monitored before, during, and after each treatment with a spectrometer (SA Instruments, model H-20, Metuchen, NJ).

The treatment was given either by surface radiation or interstitially. Originally, fiber tips were straight cut and polished for both surface and insertion techniques. Later, fibers with a microlens on the tip were used for surface irradiation (Laser Guide, Santa Barbara, Calif, or Laser Medical Research Foundation, Columbus, Ohio), and cylinder-diffusing fibers were used for interstitial therapy when the tumor was large enough. Interstitial insertion was made through a suitable hypodermic needle or directly into the tumor. The quarts fibers were coupled to the dye laser either directly or through a beam splitter (Photofrin Medical Inc, Cheektowaga, NY) to allow us to use simultaneously up to four fibers for interstitial implantation.

All patients were observed daily in the hospital for at least four days after PDT. After discharge, they were seen at least weekly for one month, at least every two to three months for one year, and periodically thereafter. Interim contact and follow-up were made by the primary physician and by telephone calls to the patients.

Tumor response to treatment was evaluated as follows: complete response, no clinical evidence of tumor; partial response, more than a 50% reduction in the number or size of tumors; some response, tumor reduction of 20% to 50%; no response, tumor reduction of 0% to 20%; and progression.

The adjacent skin was evaluated for erythema, edema, blisters, necrosis, and pain. The time and location of residual tumor and the development of new tumors were recorded. Photographs were taken routinely for more accurate comparison.

This study also investigated the accuracy with which power densities are currently measured, thereby affecting the ability to estimate light doses delivered. Surface power densities were measured with three different techniques: (1) the Coherent radiometer (Coherent, model 210, Palo Alto, Calif) placed on the surface; (2) the Yellow Springs radiometer (Yellow Springs Instruments, model 65A, Yellow Springs, Ohio) placed on the surface; and (3) the total power measured at the tip of the fiber with the Coherent 210 radiometer divided by the area of the circle of light at the surface of the plane being irradiated. The power density at many treatment sites was measured with all three techniques for later comparison.

For interstitial therapy, the total power was measured from the fiber tip with a Coherent 210 radiometer for straight-tipped fibers. When a cylinder fiber was used, the length of the diffusing tip was measured, and the total power output was determined by using an integrating sphere radiometer (United Detector Technology, model 61, Hawthorne, Calif). The power was recorded on a "per centimeter of length of diffusing fiber" basis.

The number of joules per centimeter squared for surface irradiation was calculated from the power density and the time of exposure. The interstitial treatment dose was measured by the total number of joules from straight-tipped fibers or from the joules per centimeter of diffusing length when cylinder fibers were used.

The power density configuration of the output from the different fiber types was also measured. With the fiber held at a fixed distance from the radiometer, the power density was measured with the Yellow Springs radiometer at 1.0-cm distances along the x and y axes through the center of the light circle. Changes in the power densities at varying distances from the fiber tips were also measured.

RESULTS

Clinical Findings

Clinical results are presented in Table 1. One month after treatment, 48 (67%) of 72 treatment sessions resulted in complete responses, and 19 (26%) resulted in partial responses. Fifteen patients were examinable 12 months after treatment. In this subgroup, one month after therapy, 31 treatment sessions were evaluated as complete responses, 15 (48%) of which retained this status at one year after treatment. (Some patients developed obvious new lesions in the field of treatment many months after the treatment, although the original lesions remained as complete responses. These are not included in the list of areas reported, showing no recurrence at six or 12 months.)

Many patients had multiple lesions in the treated areas, and many had end-stage disease and died before the six- or 12-month evaluation could be made. Nevertheless, several of these patients' lesions were categorized as complete responses at the time of patient death. Three patients who

Fig 1.—Left, Squamous cell cancer of eyelid. Right, Two years after two 8-minute surface treatments of photodynamic therapy. Five years after treatment, there has been no evidence of disease. Patient continues to have no disease.

Fig 2.—Top left, Metastatic breast cancer metastases to skin. Entire areas outlined were treated with 630-nm light. Top right, Four days after photodynamic therapy, tumors were reddish brown and necrotic. Bottom, Six months after photodynamic therapy, there was no clinical evidence of disease in treated areas.

Fig 3.—Left, Basal cell metastases to neck. Right, Three months after surface and interstitial photodynamic therapy, tumor has been completely eradicated.

Fig 4.—Left, Skin and subcutaneous metastatic breast cancer. Right, Twenty-four hours after photodynamic therapy, tumors were black and necrotic, while adjacent skin areas were only hyperemic.

Figure 1.

Figure 2.

Figure 3.

Figure 4.

Fig 5.—Graph shows power densities delivered by straight-tipped fiber (polished) with 630-nm light, as measured with Yellow Springs radiometer. Output from this type of fiber tip is nonhomogeneous and results in overtreatment of central area with necrosis and pain and in undertreatment of periphery.

had severe chronic pain obtained relief within three weeks after treatment. Two patients with adjuvant PDT at the time of surgical excision of their tumor had histologically proved tumors at the margins of the resections. After PDT, these lesions achieved complete responses, lasting up to 24 and 12 months.

Figure 1 shows a squamous cell cancer before PDT (left) and two years after two 8-minute surface treatments (right). The patient is still alive five years after treatment with no evidence of disease. Figure 2 shows metastatic breast cancer to skin (top left); four days after PDT, the tumors were reddish brown and necrotic (top right); and six months after PDT, no tumors were visible or palpable (bottom). Figure 3 shows metastatic basal cell cancer before (left) and three months after two treatments (right). Figure 4 shows metastatic breast cancer before PDT (left) and 24 hours after treatment (right). The nodules are black and necrotic, while the adjacent skin is not damaged. These examples demonstrate that PDT for cutaneous and subcutaneous malignant neoplasms can produce long-term complete responses.

No patients experienced either febrile or allergic reactions to the injection of any of the sensitizers. However, postoperative solar photosensitivity can last up to six months from one injection of hematoporphyrin derivative or dihematoporphyrin ether, although it is usually safe for patients to begin exposure cautiously after one month. Sunscreens offer some protection, but patients have been "burned" through white clothing at two and six months.

The effect of the light dose on the adjacent skin varied with skin type, location, and condition, and it was more intense on subsequent injections and treatment, even several months apart, especially on previously treated areas. The ideal reaction was slight erythema to the adjacent skin, no pain, and blue-black necrosis of the tumor within 48 hours after therapy. With a homogeneous light source and the power density measured from the total output delivered divided by the area of the spot, we obtained complete responses with doses in the range of 20 to 30 J/cm.² Doses greater than this range almost invariably produced unacceptable pain and necrosis of the adjacent skin in white patients. If areas were overtreated, tissue blanching occurred within hours after treatment, and tissue appeared to be completely devascularized and developed full-thickness skin necrosis and dry gangrene and

eschar formation. Essentially, whatever became white turned black soon after. Other sequences of reaction to overtreatment of the skin were erythema and/or edema, violaceous discoloration, dry brown-black eschar, and demarcation. This progression took two to 14 days, depending on the light dose and was accompanied by a "burning" pain. Three patients had to be readmitted to the hospital because of this complication.

The skin reaction to PDT given two days after injection was greater than when given on day 3. The reaction on days 3 through 6 clinically appeared to be the same for similar high doses. The color, density, and size of the tumor also affect the reaction.

Tumors over 2.0 cm thick are only partially destroyed by surface irradiation. We feel it is better to "debulk" or excise these larger tumors and treat the remaining tissue bed with PDT, either subsequently or at the time of surgery

Fig 6.—Effect of varying distance from lens fiber (1.6 W of 630 nm) that has angle of divergence of 20° on power density. Power density decreases approximately 4% for each centimeter of distance.

Fig 7.—Skin surface temperatures using different power densities during photodynamic therapy.

while the area is exposed. The use of PDT as an adjuvant in this setting may be an aid in decreasing the amount of surgery required to "get around" the lesion. Two patients who underwent tumor excision with concomitant PDT had no recurrence of tumor for over one year, although the margins of the resected specimen showed pathologic evidence of tumor.

Due to the inflammatory reaction, it is difficult to evaluate the response only one month after treatment. Two tumors evaluated as partial responses at one month were reevaluated to be complete responses at six months. One patient with a clinical complete response at one month had histologic viable tumor subcutaneously when the area was excised for pain relief. The only way to evaluate the reaction truly would be to excise the areas treated and examine them histologically; obviously, for these patients, that was generally not feasible or purposeful. Since the cancerous periphery of malignant ulcers necrosed, some actually became larger by the end of one month, although the edges became sharply demarcated as though excised with a scalpel. Large, noncancerous ulcers require several months to heal. Thus, prolonged follow-up is necessary to evaluate the treatment results truly. Early re-treatment should be done as soon as residual or recurrent cancer is identified. We were able to obtain long-term complete responses (over two years) in some patients after only one re-treatment.

Power Density Measurements

Currently, investigators are using different techniques to measure power densities. As demonstrated in this study, these techniques produce differences in power density measurements. Powers from straight-tipped fibers or from lens-tipped fibers, measured with the integrating sphere, were 10% to 20% greater than powers that were measured with the Coherent 210 radiometer. Even powers of two different Coherent radiometers gave different power readings, varying from 5% to 15%. It is extremely important, therefore, to calibrate these instruments periodically. Especially problematic is the nonhomogeneity of many deliv-

ery sources that gives a higher power density in the center of the target, resulting in an undertreated periphery and central necrosis. Nonhomogeneous light sources have led several investigators to report recurrence or incomplete tumor destruction in the periphery of the treated area.[10,11,19] This phenomenon is demonstrated in Fig 5. The power densities delivered by a straight-tipped fiber, as measured with a Yellow Springs radiometer, are plotted on the x axis. A similar graph can be made for the y axis. The output from a straight-tipped fiber is nonhomogeneous and results in overtreatment of the central area with necrosis and pain and in undertreatment of the periphery.

Table 2 compares power densities measured at the time of treatment by using a Yellow Springs or a Coherent 210 radiometer for direct measurements and by the area of the circle technique for a homogeneous lens and a nonhomogeneous fiber tip light source. The most convenient technique to measure the power density is from the total power output at the tip and the area of the circle of light at the treated surface, especially for intraoperatively sterile areas. This requires a homogeneous lens light source. The Yellow Springs radiometer provided the most convenient spot power density readings. By holding the Coherent 210 radiometer on the surface that was being irradiated, higher power densities were produced than by the other techniques since the radiometer was closer to the light source. Moreover, since the incident beam should be perpendicular to the radiometer, this technique is difficult to use to measure the power density on irregular surfaces. The power density can decrease significantly within a few centimeters from the fiber tip when a lens fiber with a rapidly diverging angle is used. This may cause a significant difference in the dose delivered to surfaces with irregular contours. Figure 6 shows the effect on the power density of varying the distance from a lens fiber that has an angle of divergence of approximately 20°. The power density decreases approximately 4% for each centimeter of distance. The output, wavelength, and homogeneity of the light must be checked and monitored during each treatment to establish accurate reference data. Homogeneous lens fibers can become nonhomogeneous with use.

Reports of reactions with specific light doses cannot be compared on a dose basis alone. The exact technique of measuring the power density must also be reported. Only then will we be able to compare accurately data collected from various centers that conduct PDT studies.

Temperature Changes

With power densities in the 10- to 200-mW/cm² range, the reaction is reciprocal and depends on the total dose given and not the power density. Above this, however, thermal changes may occur, and these temperature elevations are due to power density. Hyperthermia can be produced from the laser light itself if the power density is high enough. When PDT was performed three days after the injection of 2.0 mg/kg of dihematoporphyrin ether, the temperature 2.0 mm under the surface of a skin cancer rose from 28.8°C to 31.6°C when the surface was exposed to a power density of 29 mW/cm². The temperature returned to 29.4°C immediately when the light was turned off. Figure 7 shows the skin surface temperatures with different power densities during PDT.

COMMENT

Based on this study, we were able to draw the following conclusions regarding PDT.

1. Photodynamic therapy for cutaneous and subcutaneous cancers provides a complete response in some patients that lasts up to five years.
2. The reaction to PDT two days after injection of the sensitizer was greater than at three days. From three to six days, however, the reaction appeared to be clinically similar.
3. Solar photosensitivity can last up to six months.
4. The average power density is not adequate if a nonhomogeneous light source is used; therefore, a straight-cut quartz fiber, which delivers a nonhomogeneous light, is not acceptable for surface irradiation.
5. Using a homogeneous light source to measure the power density by calculating the area irradiated and the total power output, a dose of more than 20 to 30 J/cm² causes excessive necrosis of normal skin in white patients.
6. Different techniques of measuring power density yield varying results, so the technique used must be reported.
7. Clinically, the photodynamic reaction is reciprocal and depends on the dose and not the power density, as long as the power density is less than approximately 200 mm/cm².
8. The laser light itself can cause hyperthermia, depending on the power density.
9. Adjuvant PDT for tumor areas that showed a "tumor in a resected margin" pathologically gave complete responses that lasted up to 24 months.

Cipro®

(ciprofloxacin HCl/Miles)

A REVOLUTIONARY ORAL ANTIMICROBIAL

Cipro®

(ciprofloxacin HCl/Miles)

CONVENIENT ORAL
***B.I.D.* DOSAGE**

250 mg, 500 mg,
and 750 mg tablets

POWER

OF PARENTERALS

- **Highly active in vitro against a broad range of gram-positive and gram-negative pathogens, including *Pseudomonas aeruginosa* and methicillin-resistant *Staphylococcus aureus****
- **For treatment of infections† in the:**
  - **lower respiratory tract**
  - **urinary tract**
  - **skin/skin structure**
  - **bones and joints**
- **Well tolerated – low incidence of side effects**

For further information, contact the Miles Information Service: 1-800-642-4776. (In VA, call collect: 703-391-7888.)

*In vitro activity does not necessarily imply a correlation with in vivo results.

†Due to susceptible strains of indicated pathogens. See indicated organisms in Prescribing Information.

CIPRO® SHOULD NOT BE USED IN CHILDREN, ADOLESCENTS, OR PREGNANT WOMEN.

A history of hypersensitivity to ciprofloxacin is a contraindication to its use. A history of hypersensitivity to other quinolones may also contraindicate the use of ciprofloxacin.

Before prescribing Cipro®, please see Brief Summary of Prescribing Information.

Severe/Complicated Infections*: 750 mg q12h

CIPRO®
(ciprofloxacin hydrochloride/Miles)
TABLETS

BRIEF SUMMARY
CONSULT PACKAGE INSERT FOR FULL PRESCRIBING INFORMATION

INDICATIONS AND USAGE

Cipro® is indicated for the treatment of infections caused by susceptible strains of the designated microorganisms in the conditions listed below.

Lower Respiratory Infections caused by *Escherichia coli, Klebsiella pneumoniae, Enterobacter cloacae, Proteus mirabilis, Pseudomonas aeruginosa, Haemophilus influenzae, Haemophilus parainfluenzae,* and *Streptococcus pneumoniae.*

Skin and Skin Structure Infections caused by *Escherichia coli, Klebsiella pneumoniae, Enterobacter cloacae, Proteus mirabilis, Proteus vulgaris, Providencia stuartii, Morganella morganii, Citrobacter freundii, Pseudomonas aeruginosa, Staphylococcus aureus* (penicillinase and nonpenicillinase-producing strains), *Staphylococcus epidermidis,* and *Streptococcus pyogenes.*

Bone and Joint Infections caused by *Enterobacter cloacae, Serratia marcescens,* and *Pseudomonas aeruginosa.*

Urinary Tract Infections caused by *Escherichia coli, Klebsiella pneumoniae, Enterobacter cloacae, Serratia marcescens, Proteus mirabilis, Providencia rettgeri, Morganella morganii, Citrobacter diversus, Citrobacter freundii, Pseudomonas aeruginosa, Staphylococcus epidermidis,* and *Streptococcus faecalis.*

Infectious Diarrhea caused by *Escherichia coli* (enterotoxigenic strains), *Campylobacter jejuni, Shigella flexneri,** and *Shigella sonnei** when antibacterial therapy is indicated.

*Efficacy for this organism in this organ system was studied in fewer than 10 infections.

Appropriate culture and susceptibility tests should be performed before treatment in order to isolate and identify organisms causing infection and to determine their susceptibility to ciprofloxacin. Therapy with Cipro® may be initiated before results of these tests are known; once results become available appropriate therapy should be continued. As with other drugs, some strains of *Pseudomonas aeruginosa* may develop resistance fairly rapidly during treatment with ciprofloxacin. Culture and susceptibility testing performed periodically during therapy will provide information not only on the therapeutic effect of the antimicrobial agent but also on the possible emergence of bacterial resistance.

CONTRAINDICATIONS

A history of hypersensitivity to ciprofloxacin is a contraindication to its use. A history of hypersensitivity to other quinolones may also contraindicate the use of ciprofloxacin.

WARNINGS

CIPROFLOXACIN SHOULD NOT BE USED IN CHILDREN, ADOLESCENTS, OR PREGNANT WOMEN. The oral administration of ciprofloxacin caused lameness in immature dogs. Histopathological examination of the weight-bearing joints of these dogs revealed permanent lesions of the cartilage. Related drugs such as nalidixic acid, cinoxacin, and norfloxacin also produced erosions of cartilage of weight-bearing joints and other signs of arthropathy in immature animals of various species (SEE ANIMAL PHARMACOLOGY SECTION IN FULL PRESCRIBING INFORMATION).

PRECAUTIONS

General: As with other quinolones, ciprofloxacin may cause central nervous system (CNS) stimulation, which may lead to tremor, restlessness, lightheadedness, confusion, and very rarely to hallucinations or convulsive seizures. Therefore, ciprofloxacin should be used with caution in patients with known or suspected CNS disorders, such as severe cerebral arteriosclerosis or epilepsy, or other factors which predispose to seizures (SEE ADVERSE REACTIONS).

Quinolones may also cause anaphylactic reactions and cardiovascular collapse. Anaphylactic reactions may require epinephrine and other emergency measures.

Crystals of ciprofloxacin have been observed rarely in the urine of human subjects but more frequently in the urine of laboratory animals. Crystalluria related to ciprofloxacin has been reported only rarely in man, because human urine is usually acidic. Patients receiving ciprofloxacin should be well hydrated, and alkalinity of the urine should be avoided. The recommended daily dose should not be exceeded. Alteration of the dosage regimen is necessary for patients with impairment of renal function (SEE DOSAGE AND ADMINISTRATION SECTION IN FULL PRESCRIBING INFORMATION).

Drug Interactions: Concurrent administration of ciprofloxacin with theophylline may lead to elevated plasma concentrations of theophylline and prolongation of its elimination half-life. This may result in increased risk of theophylline-related adverse reactions. If concomitant use cannot be avoided, plasma levels of theophylline should be monitored and dosage adjustments made as appropriate.

Antacids containing magnesium hydroxide or aluminum hydroxide may interfere with the absorption of ciprofloxacin, resulting in serum and urine levels lower than desired; concurrent administration of these agents with ciprofloxacin should be avoided.

Probenecid interferes with the renal tubular secretion of ciprofloxacin and produces an increase in the level of ciprofloxacin in the serum. This should be considered if patients are receiving both drugs concomitantly.

As with other broad-spectrum antibiotics, prolonged use of ciprofloxacin may result in overgrowth of nonsusceptible organisms. Repeated evaluation of the patient's condition and microbial susceptibility testing is essential. If superinfection occurs during therapy, appropriate measures should be taken.

Information for Patients: Patients should be advised that ciprofloxacin may be taken with or without meals. The preferred time of dosing is two hours after a meal. Patients should also be advised to drink fluids liberally and not take antacids containing magnesium or aluminum concomitantly or within two hours after dosing. Ciprofloxacin may cause dizziness or lightheadedness; therefore patients should know how they react to this drug before they operate an automobile or machinery or engage in activities requiring mental alertness or coordination.

Carcinogenesis, Mutagenesis, Impairment of Fertility: Eight *in vitro* mutagenicity tests have been conducted with ciprofloxacin and the test results are listed below:

- Salmonella/Microsome Test (Negative)
- *E. coli* DNA Repair Assay (Negative)
- Mouse Lymphoma Cell Forward Mutation Assay (Positive)
- Chinese Hamster V_{79} Cell HGPRT Test (Negative)
- Syrian Hamster Embryo Cell Transformation Assay (Negative)
- *Saccharomyces cerevisiae* Point Mutation Assay (Negative)
- *Saccharomyces cerevisiae* Mitotic Crossover and Gene Conversion Assay (Negative)
- Rat Hepatocyte DNA Repair Assay (Positive)

Thus, two of the eight tests were positive, but the following three *in vivo* test systems gave negative results:

- Rat Hepatocyte DNA Repair Assay
- Micronucleus Test (Mice)
- Dominant Lethal Test (Mice)

Long-term carcinogenicity studies in animals have not yet been completed.

Pregnancy – Pregnancy Category C: Reproduction studies have been performed in rats and mice at doses up to six times the usual daily human dose and have revealed no evidence of impaired fertility or harm to the fetus due to ciprofloxacin. In rabbits, as with most antimicrobial agents, ciprofloxacin (30 and 100 mg/kg orally) produced gastrointestinal disturbances resulting in maternal weight loss and an increased incidence of abortion. No teratogenicity was observed at either dose. After intravenous administration, at doses up to 20 mg/kg, r maternal toxicity was produced, and no embryotoxicity or teratogenicity was observed. There are, however, r adequate and well-controlled studies in pregnant women. SINCE CIPROFLOXACIN, LIKE OTHER DRUGS IN IT CLASS, CAUSES ARTHROPATHY IN IMMATURE ANIMALS, IT SHOULD NOT BE USED IN PREGNANT WOME (SEE WARNINGS).

Nursing Mothers: It is not known whether ciprofloxacin is excreted in human milk; however, it is known th ciprofloxacin is excreted in the milk of lactating rats and that other drugs of this class are excreted in human mi Because of this, and because of the potential for serious adverse reactions from ciprofloxacin in nursing infants decision should be made to discontinue nursing or to discontinue the drug, taking into account the importance the drug to the mother.

Pediatric Use: Ciprofloxacin should not be used in children because it causes arthropathy in immature anima (SEE WARNINGS).

ADVERSE REACTIONS

Ciprofloxacin is generally well tolerated. During clinical investigation, 2,799 patients received 2,868 courses the drug. Adverse events that were considered likely to be drug related occurred in 7.3% of courses, possib related in 9.2%, and remotely related in 3.0%. Ciprofloxacin was discontinued because of an adverse event 3.5% of courses, primarily involving the gastrointestinal system (1.5%), skin (0.6%), and central nervous syste (0.4%).

The most frequently reported events, drug related or not, were nausea (5.2%), diarrhea (2.3%), vomiting (2.09 abdominal pain/discomfort (1.7%), headache (1.2%), restlessness (1.1%), and rash (1.1%).

Additional events that occurred in less than 1% of ciprofloxacin courses are listed below. Those typical quinolones are italicized.

GASTROINTESTINAL: *(See above),* painful oral mucosa, oral candidiasis, dysphagia, intestinal perforatio gastrointestinal bleeding.

CENTRAL NERVOUS SYSTEM: *(See above), dizziness, lightheadedness, insomnia, nightmares, hallucin tions, manic reaction, irritability, tremor, ataxia, convulsive seizures, lethargy, drowsiness, weaknes malaise, anorexia, phobia, depersonalization, depression, paresthesia.*

SKIN/HYPERSENSITIVITY: *(See above), pruritus, urticaria, photosensitivity, flushing, fever, chil angioedema, edema of the face, neck, lips, conjunctivae or hands,* cutaneous candidiasis, hyperpigment tion, erythema nodosum.

Allergic reactions ranging from urticaria to anaphylactic reactions have been reported.

SPECIAL SENSES: *blurred vision, disturbed vision, (change in color perception, overbrightness of light decreased visual acuity, diplopia, eye pain, tinnitus, bad taste.*

MUSCULOSKELETAL: *joint or back pain, joint stiffness,* achiness, neck or chest pain, flare-up of gout.

RENAL/UROGENITAL: *interstitial nephritis, renal failure,* polyuria, urinary retention, urethral bleedir vaginitis, acidosis.

CARDIOVASCULAR: palpitations, atrial flutter, ventricular ectopy, syncope, hypertension, angina pector myocardial infarction, cardiopulmonary arrest, cerebral thrombosis.

RESPIRATORY: epistaxis, laryngeal or pulmonary edema, hiccough, hemoptysis, dyspnea, bronchospas pulmonary embolism.

Most of these events were described as only mild or moderate in severity, abated soon after the drug w discontinued, and required no treatment.

In several instances, nausea, vomiting, tremor, restlessness, agitation, or palpitations were judged investigators to be related to elevated plasma levels of theophylline possibly as a result of a drug interaction wi ciprofloxacin.

Adverse Laboratory Changes: Changes in laboratory parameters listed as adverse events without regard drug relationship.

Hepatic – Elevations of: ALT (SGPT) (1.9%), AST (SGOT) (1.7%), alkaline phosphatase (0.8%), LDH (0.4% serum bilirubin (0.3%).

Hematologic – eosinophilia (0.6%), leukopenia (0.4%), decreased blood platelets (0.1%), elevated blo platelets (0.1%), pancytopenia (0.1%).

Renal – Elevations of: Serum creatinine (1.1%), BUN (0.9%).

CRYSTALLURIA, CYLINDRURIA, AND HEMATURIA HAVE BEEN REPORTED.

Other changes occurring in less than 0.1% of courses were: Elevation of serum gammaglutamyl transferas elevation of serum amylase, reduction in blood glucose, elevated uric acid, decrease in hemoglobin, anem bleeding diathesis, increase in blood monocytes, and leukocytosis.

OVERDOSAGE

Information on overdosage in humans is not available. In the event of acute overdosage, the stomach should emptied by inducing vomiting or by gastric lavage. The patient should be carefully observed and given support treatment. Adequate hydration must be maintained. In the event of serious toxic reactions from overdosag hemodialysis or peritoneal dialysis may aid in the removal of ciprofloxacin from the body, particularly if re function is compromised.

DOSAGE AND ADMINISTRATION

The usual adult dosage for patients with urinary tract infections is 250 mg every 12 hours. For patients w complicated infections caused by organisms not highly susceptible, 500 mg may be administered every 12 hou

Respiratory tract infections, skin and skin structure infections, and bone and joint infections may be treat with 500 mg every 12 hours. For more severe or complicated infections, a dosage of 750 mg may be given every hours.

The recommended dosage for infectious diarrhea is 500 mg every 12 hours.

In patients with renal impairment, some modification of dosage is recommended (SEE DOSAGE AN ADMINISTRATION SECTION IN FULL PRESCRIBING INFORMATION).

HOW SUPPLIED

Cipro® (ciprofloxacin HCl/Miles) is available as tablets of 250 mg, 500 mg, and 750 mg in bottles of 50, and Unit-Dose packages of 100 (SEE FULL PRESCRIBING INFORMATION FOR COMPLETE INFORMATION).

***Due to susceptible strains of indicated pathogens. See indicated organisms in Prescribing Information.**

Antioxidants vs Carotenoids

Inhibitors or Promoters of Experimental Colorectal Cancers

Thomas A. Colacchio, MD; Vincent A. Memoli, MD; Laurie Hildebrandt

• The organospecific, 1,2-dimethylhydrazine-induced murine tumor model was used to test the effects on tumor formation of the following dietary supplements: (1) ascorbic acid, 7% per weight; (2) alpha tocopherol, 1% per weight; (3) beta carotene, 1% per weight; and (4) canthazanthin, 1% per weight. Following a four-week dietary acclimation, a 16-week 1,2-dimethylhydrazine induction, and a four-week hiatus, the animals were killed, underwent autopsies, and tumor formation was recorded. The antioxidant supplements of ascorbic acid and alpha tocopherol resulted in a significant decrease in tumor formation when compared with control groups. In contrast, the beta carotene group showed no difference in tumor formation, and canthazanthin, a non–provitamin A carotenoid, resulted in an increase in tumor formation when compared with controls. In addition, the K-gel powder control diet (a carrier medium for alpha tocopherol acetate) had a significantly higher rate of tumor formation than the regular chow and placebo beadlet control diets. In sum, ascorbic acid and alpha tocopherol demonstrated a clear chemopreventive effect, whereas beta carotene had no effect, and canthazanthin appeared to function as a promoter in this organospecific tumor model.

(*Arch Surg* 1989;124:217-221)

Colorectal carcinoma is the most common visceral cancer in the United States, with a rising annual incidence and mortality that are predicted to be 147 000 new cases and more than 60 000 deaths for the year 1988.[1] Despite the increasing efforts of educational programs to improve early diagnosis, there has been little change in survival, and these incidence figures represent an increase of more than 25% over the past three decades. Although the etiology of this disease is multifactorial, environmental factors with specific reference to regional dietary habits play a major role.[2] In addition, high-risk populations in North America have been found to harbor fecal mutagenic substances,[3-5] and some studies have suggested that dietary factors may influence these by affecting either the actual amount of carcinogen intake or the formation of mutagenic substances in vivo.[6,7]

A broad range of compounds has been used in various tumor models to study the potential inhibition of chemical carcinogenesis. As a result of these studies and the available epidemiologic data, several prospective trials are currently under way to evaluate the effect of certain dietary supplements on the presence and level of fecal mutagens and the formation of metachronous colorectal neoplasms. The antioxidants, ascorbic acid and alpha tocopherol, and the provitamin A carotenoid, beta carotene, are among the supplements currently being evaluated. Unfortunately, the reported efficacy of these compounds as chemopreventive agents in various tumor models is inconclusive. This study reports a series of experiments designed to test the chemopreventive efficacy of ascorbic acid, alpha tocopherol, beta carotene, and canthazanthin in preventing tumor formation in an organospecific murine model utilizing symmetric 1,2-dimethylhydrazine.

MATERIALS AND METHODS

Tumor Model

Weanling male Holtzman rats (Holtzman Company, Madison, Wis) were housed in individual cages in the Dartmouth Medical School Animal Care Facility, Hanover, NH, using a standard 12-hour light/dark cycle. After a four-week dietary acclimation period, weekly subcutaneous injections of 1,2-dimethylhydrazine were begun. (Symmetric 1,2-dimethylhydrazine, Sigma Chemical Co, St Louis, was dissolved in phosphate-buffered saline solution and corrected to a pH of 7.0 with 10N sodium hydroxide.) The dose schedule was 30 mg/kg per week injected subcutaneously for 16 weeks, resulting in a total dose of 480 mg/kg.

Four weeks after the final injection, the animals were killed and autopsies were performed. At necropsy, the thoracic and abdominal cavities were examined for evidence of ascites and primary or metastatic tumor formation. In addition, the entire intestinal tract from the duodenum to the anus was removed, opened, and examined for tumor formation. Biopsy specimens of all suspected lesions were prepared and stained using standard histologic techniques with hematoxylin-eosin. The biopsy slides were then evaluated microscopically and diagnosed as adenoma, carcinoma, or other (nonneoplastic). In addition, biopsy specimens of suspected metastatic lesions were similarly analyzed histopathologically. The number of primary lesions, their location, and the presence of metastatic deposits were then recorded for each animal. Only tumors confirmed histopathologically were included.

Accepted for publication Oct 13, 1988.

Supplemental Diets

The animals were divided into groups and placed on prescribed diets with water ad libitum during the initial four-week acclimation period and they were maintained on these for the entire course of the study. There were four supplemental diets studied: (1) regular powdered chow (Purina) with 7% per weight ascorbic acid (J. T. Baker Chemical Co., Phillipsburg, NJ); (2) regular pelleted chow (Dyets Inc, Bethlehem, Pa) with 1% per weight alpha tocopherol (1.49% per weight racemic DL-alpha tocopherol acetate in K-gel powder carrier medium, Hoffmann-LaRoche Inc, Nutley, NJ); (3) regular pelleted chow with 1% per weight beta carotene (in beadlet form, Hoffmann-LaRoche Inc); and (4) regular pelleted chow with 1% per weight canthazanthin (in beadlet form, Hoffmann-La Roche Inc). These were matched with control diets containing the appropriate carrier compounds: (1) regular chow (pelleted and powdered); (2) regular pelleted chow with 1.49% per weight K-gel powder; and (3) regular pelleted chow with 10% per weight placebo beadlets (beta carotene and canthazanthin are prepared as 10% per weight beadlets).

Statistical Analysis

The results were analyzed by group according to the presence or absence of tumor formation, the location of the tumor (small bowel vs colon), and the histologic characteristics of the tumor (adenoma vs carcinoma). Group means with SDs were then calculated. These means were compared using the χ^2 test and Student's *t* test, with statistical significance being a *P* value less than .01.[8]

*DMBA indicates dimethylbenzanthracene; BP, benzo(a)pyrene.

RESULTS

The mean weight gain over the 24-week period varied somewhat between the various supplement groups (279.8 to 339.9 g); generally, animals in 1,2-dimethylhydrazine–induced groups have a lower weight gain than those in noninduced groups.[9] The only significant difference noted between the supplement and nonsupplement 1,2-dimethylhydrazine–induced groups was between the canthazanthin–1,2-dimethylhydrazine (279.8 g) and placebo beadlet–1,2-dimethylhydrazine (325.6 g) groups ($P = .0013$).

The results of 1,2-dimethylhydrazine induction on tumor formation in the control groups (regular chow, placebo beadlet, and K-gel powder) are shown in Tables 1 through 3. Although there is no spontaneous intestinal tumor formation in these animals, this relatively high-dose induction schedule resulted in 100% tumor formation in the control groups at 20 weeks. Almost all these animals have cancers and the majority of these tumors are in the colon. There were significantly more tumors found in both the colon and small intestine of the K-gel powder group when compared with the regular chow and placebo beadlet groups. In addition, there were significantly more colon tumors found in the placebo beadlet group when compared with the regular chow group.

A comparison of the results of 1,2-dimethylhydrazine induction in the ascorbic acid supplement and regular chow groups is shown in Table 1. There was a highly significant difference in the number of animals with tumors and the number of tumors per animal between these two groups. This was noted in both the colon and, although less striking, in the small bowel. A similar trend was found when the alpha tocopherol group was compared with the K-gel powder group (Table 2). In this instance, however, the differences were more pronounced in the small bowel rather than in the colon.

Table 3 shows the comparison between the beta carotene supplement group and the placebo beadlet group. There was no difference in the numbers of animals with tumors or cancers or in the number of tumors or cancers per animal noted. Similarly, no differences were found either in the colon or small bowel. In contrast to this, Table 4 shows the difference between the canthazanthin supplement group and the placebo beadlet group; there is a striking increase in both the number of tumors and the number of cancers found in the canthazanthin group. The breakdown shows that there are more tumors and cancers in both the colon and small bowel, but these individual comparisons fall short of statistical significance.

COMMENT

Many compounds of varying toxicity have been used as chemopreventive agents in several animal tumor models, but the results of these studies have often been inconclusive or contradictory. Two basic mechanisms of action have

*UV indicates ultraviolet; DMBA, dimethylbenzanthracene.

been proposed for these agents: (1) an alteration of the metabolism of the carcinogen by decreased activation and/or increased detoxification; and (2) the scavenging of active molecular species of the carcinogens to prevent them from reaching critical target sites in the cells.[10] The exertion of this scavenging effect thereby protecting the cells from attack has been the rationale for the chemopreventive use of antioxidant compounds such as ascorbic acid and alpha tocopherol. The ability to inhibit the formation of free radicals and to quench singlet-excited oxygen has led some to postulate the potential for a chemopreventive effect by the carotenoids beta carotene and canthazanthin.[11] In addition, the provitamin A activity of beta carotene might also inhibit tumor formation (1) by exerting hormonelike effects on the cells later in the genesis of cancer, thus returning them to a more differentiated state or (2) possibly by increasing the immunocompetence of the host.

Ascorbic acid has been an extensively studied compound for its potential as a chemopreventive agent (Table 5).[9,12-21] It has been evaluated by several authors in various tumor models with conflicting results. In two studies that used the organospecific carcinogen 1,2-dimethylhydrazine in a murine model, the authors showed no protective effects when it was used as a single agent in a multidose induction model.[13,20] These results clearly differ from the dramatic protective effects reported herein that are highlighted by the complete absence of tumor formation in almost seven (25%) of the animals in the supplement group. Possible explanations for this include the following: (1) differences in the dose and form of ascorbic acid used (0.25% and 1.0% per weight of sodium ascorbate as reported by Reddy et al[13] and 25 to 500 mg/kg per day as reported by Jones et al[20]); (2) inherent differences in the animal model used or in the schedule and total dose of 1,2-dimethylhydrazine given; (3) differences in the length of the preinduction acclimation period (ten days in the study of Jones et al and two weeks in the study of Reddy et al).

Fewer studies have been done using alpha tocopherol (Table 6),[22-29] but the results have also been conflicting, especially in the 1,2-dimethylhydrazine murine model. Cook and McNamara[22] found that a vitamin E–supplemented diet (0.06% per weight) resulted in a decrease in tumor formation when compared with an alpha tocopherol–deficient diet (0.0001% per weight); however, these groups were not compared with a control group receiving a regular diet. Using a mammary model, Ip[28] found that alpha tocopherol deficiency led to an increase in tumor formation, whereas alpha tocopherol supplements resulted in no difference from the control group (0.0003% per weight vs 0.000075% per weight and 0.1% per weight). In contrast, Toth and Kashinath[25] found that a high-dose alpha tocopherol–supplemented diet (4% per weight) actually resulted in an increase in tumor formation in a 1,2-dimethylhydrazine mouse model. Once again, inherent differences in the model used, the dose of alpha tocopherol supplementation, and/or the composition of the diet in the control group are the likely explanations for the differences between these other studies and the findings reported herein. Although the reason for the increase in tumor formation occurring in the group receiving the K-gel powder placebo diet is unclear, there was a marked decrease in tumor formation in the group maintained on the diet supplemented with K-gel powder containing 1% per weight alpha tocopherol.

The carotenoids beta carotene and canthazanthin have been less extensively tested as chemopreventive agents (Table 7),[9,30-37] and, to our knowledge, there has been only one report on the use of beta carotene in a 1,2-dimethylhydrazine murine model.[8] In this initial study, it was noted that the supplemental diet containing 1% per weight of beta carotene had no effect on the induction of tumor formation. This was despite the relatively high dose of beta carotene used and the uniformly preventive effects noted by other authors in several different tumor models. In this case, the cause for the lack of efficacy may be due to the inability of beta carotene to affect the genesis of malignant transformation of mucosal intestinal cells, in addition to the factors stated previously in regard to the reported discrepancies with the study of ascorbic acid and alpha tocopherol.

Similar to beta carotene, the non–provitamin A carotenoid, canthazanthin, has been shown to be effective in preventing the photocarcinogenic enhancement of benzo(a)pyrene on skin cancer development in animals[31,35,36] and also to be photoprotective for patients with erythropoietic protoporphyria.[38,39] The effects on the organospecific 1,2-dimethylhydrazine model of a diet supplemented with 1% per weight of canthazanthin are reported herein. These results clearly demonstrate an enhancement of both tumor and cancer formation in the supplement group when compared with the placebo group. The reasons for this apparent promotional effect of canthazanthin are unknown but may well be due to specific differences in the interaction between carotenoids and various tissues (ie, squamous epithelium vs columnar epithelium) or possibly a direct

effect on the luminal surfaces of the intestine by the high concentrations of this agent, as the majority is cleared in the feces.

In summary, this report would support the continued and expanded study of the antioxidants ascorbic acid and alpha tocopherol as chemopreventive agents of colorectal neoplasms based on the effects seen in this organospecific tumor model. However, more studies need to be performed in these specific tumor model systems to justify the continued use of carotenoids in human chemopreventive studies of colorectal neoplasms.

This investigation was supported by Public Health Service grant CA35860, Washington, DC.

Discussion

Q How applicable to the treatment of human tumors do you think this is? I am not familiar with the trials of colorectal cancer but I certainly am with melanoma and I have participated in some of those trials. People would come with what appeared to be very interesting prehuman data, yet so far it has not proved to be of any benefit in randomized trials of humans that I am aware of with regard to melanoma.

A The information we have to date is that in the studies done at Memorial-Sloan Kettering, New York, by J. DeCosse, on the patients with familial polyposis, some decrease in both the numbers of polyps and the size of the polyps following treatment with ascorbic acid was observed. In addition, the group from Toronto has looked at mutagens in the stool that have been found in higher numbers and frequency in "high-risk groups" relative to low-risk groups. In this group they did find that there was a decrease in mutagen content. Whether that will translate into actual decrease in the risk for developing colorectal cancer is unclear. Our own study of mutagens with ascorbic acid and alpha tocopherol is just finishing and we hope to have that information available soon.

Finally, the most important part of what I was trying to say was my concern about the rapid transition of agents from animal and epidemiologic data into human trials. I am worried about the possibility of beta carotene being used as a promoter as opposed to its use as an inhibitor. It seems to work in skin cancer, but I am not sure the preventive effect will be carried over in humans. The caution we need to take away from this is not to be too quick to rush agents into clinical trials.

Plasma Ultrafiltration as Cancer Therapy

Alan Wile, MD

• Studies of cancer-related immunosuppression reveal the presence of low-molecular-weight (<10 kilodaltons) serum factors capable of in vitro lymphocyte suppression. Removal of suppressor factors by ultrafiltration (UF) prolongs survival in tumor-bearing rabbits. This study determined the prevalence of low-molecular-weight suppressor factors in patients with cancer and normal volunteers and evaluated safety and feasibility of UF in patients with cancer. Intact serum and serum ultrafiltrate from 32 patients with cancer and 24 normal volunteers was examined with mitogen-induced lymphocyte blastogenesis. Eleven (34%) of serum samples from patients with cancer suppressed blastogenesis, while ultrafiltrate was suppressive in 25 (78%). None of the ultrafiltrate from normal volunteers was suppressive. Six patients with cancer underwent UF in a phase I trial, completing 82 sessions. There were no therapy-related complications, and high-performance liquid chromatography showed significant (>90%) posttreatment reduction in serum suppressor factors.

(*Arch Surg* 1989;124:222-224)

Defects in cellular immune function are well documented in patients with cancer. These patients are observed to develop lymphopenia,[1] which correlates with poor prognosis.[2] Inability to mount a delayed cutaneous hypersensitivity reaction to skin test antigens with adequate numbers of lymphocytes is a frequent and grave prognostic sign, representing loss of lymphocyte function.[3] The cause of impaired lymphocyte function associated with cancer has been speculated on and is the subject of numerous articles.[4]

Of interest are reports of impaired lymphocyte function when normal lymphocytes obtained from healthy donors are placed in serum obtained from patients with cancer.[5-7] Furthermore, lymphocytes from patients with cancer regain function when placed in media devoid of these patients' serum.[8] These observations suggest that a portion of the defect in cellular immune function associated with cancer is a reversible phenomenon mediated by humoral factors.

To increase understanding of cancer-related immunosuppression, I investigated soluble immunosuppressor factors (SIFs) elaborated by tumor-bearing animals. The presence of immunosuppressive factors was observed in rats inoculated with a transplantable tumor.[9] These SIFs were secreted by host tissues associated with immune function and were not tumor products. It was determined that there were multiple low-molecular-weight (<10 kilodaltons [kd]) and several high-molecular-weight (>10 kd) factors.[10] Three of the low-molecular-weight factors were heat labile (100°C) and are presumed to be polypeptides.

The temporal sequence of elaboration of SIFs was determined by obtaining serial blood samples from tumor-bearing animals.[11] A biphasic response was observed, with serum obtained shortly after tumor inoculation enhancing splenocyte response while serum obtained later was suppressive. The suppressor effect was confined to that portion of serum passing through a filter with a molecular weight cutoff of 10 kd. The enhancing effect resided in the portion of serum retained by the ultrafilter. This observation suggested that removal of low-molecular-weight SIFs by ultrafiltration (UF) might unmask sufficient endogenous lymphocyte-enhancing activity to alter favorably the host-tumor interaction.

This hypothesis was tested by conducting continuous plasma UF in rabbits inoculated with the VX-2 carcinoma.[12] Two plasma volumes were removed with the aid of an ultrafilter (Diafilter 20; Amicon Corp, Danvers, Mass; molecular weight cutoff, 10 kd). Prolongation of survival was observed in animals undergoing a single UF therapy, especially when UF was combined with an immunoadjuvant (Detox; RIBI Immunochem Research Inc, Hamilton, Mont).

With the knowledge obtained from the animal models, a search was made for low-molecular-weight SIFs associated with human cancer. That effort comprises the substance of this article and describes the prevalence of SIFs in normal volunteers and patients with cancer, techniques used to quantitate SIFs, and a phase I trial of continuous plasma UF to remove SIFs as cancer therapy.

SUBJECTS AND METHODS

Thirty-two patients undergoing therapy for metastatic cancer consented to be blood donors for the initial portion of this study. Eleven had lymphoma, eight had breast cancer, seven had colon cancer, and two had lung cancer. Prostatic cancer, leukemia, stomach cancer, and nasopharyngeal cancer each accounted for one patient. No patient received a cytotoxic drug, including prednisone, the week before blood drawing. Twenty-four normal volunteers also donated blood.

Blood samples remained at room temperature for two hours to facilitate clotting. Serum was removed after centrifugation at 1500 rpm for ten minutes. Serum was divided into aliquots and frozen at −70°C. Aliquots of serum underwent UF by means of membranes (Amicon PM-10; Amicon Corp) with a molecular weight cutoff of 10 kd under a positive pressure of 30 psi of nitrogen. Serum ultrafiltrate was frozen at −70°C. Serum and ultrafiltrate were numerically coded and assayed in blinded fashion with normal subjects and patients with cancer mixed in sequence.

The effect of serum and ultrafiltrate on lymphocyte function was ascertained by means of a mitogen-induced lymphocyte blastogenesis assay using normal human lymphocytes as targets. Sixty milliliters of blood from a volunteer was defribrinated by mechanical means with removal of clot within five minutes of blood drawing. Remaining serum was diluted with 60 mL of phosphate-buffered saline. Aliquots were placed in centrifuge tubes containing 15 mL of Ficoll-Hypaque (Histopaque 1077; Sigma Chemical, St Louis), with care taken not to mix the serum and Ficoll-Hypaque layers. The mixture was centrifuged for 40 minutes at 1500 rpm (20°C). After centrifugation, the lymphocyte-rich interface between serum and Ficoll-Hypaque was aspirated. The interface from multiple tubes was pooled and centrifuged at 2000 rpm for ten minutes, and the supernatant was removed. The lymphocyte pellet was resuspended in 10 mL of RPMI 1640 tissue culture medium with 10% fetal calf serum. The final cell suspension was adjusted so that 180 μL contained 1×10^6 viable lymphocytes with a mitogen concentration (phytohemagglutinin; Burroughs Wellcome, Beckenham, England) of 2.5 to 5.0 mg/L.

The blastogenesis assay was conducted in microtiter test plates. Twenty microliters of serum or ultrafiltrate were added to 180 μL of the lymphocyte suspension and incubated at 37°C for 72 hours in 95% oxygen–5% carbon dioxide. After 72 hours, 10 μL of tritiated thymidine (100 mCi/L; Amersham Corp, Arlington Heights, Ill) was added to each well and incubated for an additional 18 hours. After the second incubation, the contents of the wells were aspirated, deposited on filter paper, and placed in vials containing scintillation cocktail, and radioactivity was counted in a liquid scintillation counter (one minute per sample). Samples were assayed in sextuplicate. Mean and SD were calculated. Controls included lymphocytes in normal human serum with and without phytohemagglutinin. Percentage inhibition of lymphocyte blastogenesis was calculated by dividing the results obtained with

Fig 1.—Close correlation of low-molecular-weight soluble immunosuppressor factors when quantitated by blastogenesis assay and high-performance liquid chromatographic assay (area under curve). Patients with cancer (closed squares) could be distinguished from normal volunteers (open circles) on basis of area under curve.

Fig 2.—Changes in serum levels of low-molecular-weight soluble immunosuppressor factors in single patient over time during course of ultrafiltration therapy. Although soluble immunosuppressor factors returned to high levels between treatment sessions, general trend was toward diminution in serum levels. Closed bars indicate pretreatment values; hatched bars, posttreatment values; kd, kilodaltons.

the experimental sample by the normal serum control, subtracting results from 1, and multiplying by 100.

Low-molecular-weight SIFs were quantitated by means of a high-performance liquid chromatography (HPLC) device coupled to a molecular seiving column (GPC 100 7u; Alltech Assoc Inc, Deerfield, Ill). The presence of SIFs was detected and plotted on graph paper. The area under the curve was measured with the use of a planimeter, with results expressed in arbitrary units. Comparisons were made with an external standard using known amounts of bovine insulin. Six normal individuals and eight patients with cancer underwent simultaneous quantitation of SIFs by means of the blastogenesis assay and the HPLC technique.

Six patients with cancer underwent plasma UF as a phase I trial; all failed conventional therapy and consented to participate in an experimental program approved by the University of California Irvine Human Subjects Committee (Orange, Calif). A double-lumen dialysis (Quinton) catheter was placed via the saphenous vein into the iliac vein. Delayed cutaneous hypersensitivity was ascertained before therapy and at monthly intervals.

Plasma UF was conducted in an outpatient setting. The dialysis catheter was connected to a custom UF controller (COBE Laboratories, Lakewood, Colo) mated to an ultrafilter (Amicon Diafilter 30). Ultrafiltration was achieved by withdrawing blood through the filter from heparinized patients. A negative transmembrane pressure was applied (0 to 350 mm Hg) to facilitate UF. The volume of ultrafiltrate was precisely matched with replacement saline returned to the patient with blood components retained by the filter. The goal of each treatment session was removal of three plasma volumes of ultrafiltrate. This was determined for each patient by means of a nomogram based on height, weight, hematocrit, and gender.

Blood samples were obtained from each patient before and after UF sessions for determination of SIF levels. Serum from these samples was ultrafiltered in the laboratory (Amicon PM-10 filter). The ultrafiltrate was frozen at −70°C for quantitation of SIFs by the HPLC technique.

RESULTS

The effect of intact serum from normal volunteers on mitogen-induced lymphocyte blastogenesis was averaged and used as a reference point. Ultrafiltrate from normal volunteers was suppressive (34.0% ± 31.41%; maximum, 75%). In comparison, intact serum from patients with cancer resulted in a mean suppression of 49.0% ± 38.3%, with mean suppression by ultrafiltrate of 86.8% ± 11.9%. Based on these observations, abnormal suppression was defined as 80% or greater inhibition of lymphocyte blastogenesis. Using this definition, the intact serum of 11 (34%) of the 32 patients with cancer was suppressive. Twenty-five (78%) of 32 patients with cancer possessed abnormal suppressor activity in serum ultrafiltrate, compared with none of 24 normal volunteers.

Dilution of suppressive ultrafiltrate to 1% with tissue culture medium resulted in loss of significant suppressor activity in six of 14 samples assayed in the blastogenesis assay. An additional four samples became less suppressive but did not fall below the 80% level.

Analysis of serum ultrafiltrate by HPLC methods revealed a single peak eluting at four minutes. Simultaneous examination of ultrafiltrate with the blastogenesis assay and the HPLC method demonstrated good correlation between the quantity of SIFs present as calculated by the area under the curve and the degree of inhibition of blastogenesis. It was observed that patients with cancer could be separated from normal volunteers on the basis of HPLC analysis of serum ultrafiltrate (Fig 1). In addition, values derived by the HPLC method were reproducible, while there was variability in the bioassay.

The six patients with cancer completed 82 sessions of UF, during which it was usually possible to remove three plasma volumes (5 to 10 L) in three to four hours. Flow through the system was limited by the size of the catheter lumen, but rates as high as 250 mL/min were reached. On occasion, patients experienced muscle cramps during the UF procedure. This was thought to be due to hyponatremia, and the cramps resolved when the replacement fluid of lactated Ringer's solution was supplemented to raise the sodium concentration to 154 mEq/L and the calcium concentration to 3.5 mEq/L.

Catheter-related problems were the major complications

of UF therapy. Frequent catheter clotting required intracatheter instillation of streptokinase. Daily aspirin therapy was tried, without benefit. Patients later were given warfarin sodium, aimed at maintaining prothrombin time 50% greater than control, with resolution of catheter clotting. One patient developed catheter sepsis, requiring removal of the catheter. The same patient had a second catheter placed on the opposite side, with resulting ileofemoral thrombosis.

Serum levels of SIFs were measured by means of the HPLC technique in those patients undergoing UF therapy. This examination revealed the ability of UF to remove SIFs (Fig 2). Serum levels of SIFs were decreased by more than 90% after UF. Levels of SIFs would return to near pretreatment values between UF sessions. Periodic UF was able to reduce serum levels of SIFs over time. No patient in the treatment group demonstrated significant reduction of tumor size during the two-month period of UF therapy. Of the six patients in the trial, five were anergic. No change in response to skin test antigens occurred in these patients during the trial period.

COMMENT

The initial observation was that ultrafiltrate from normal volunteers suppressed lymphocyte blastogenesis. A portion of this effect may be due to the absence of lymphokines such as interleukin 1, interleukin 2, and interferon, all of which have molecular weights greater than 10 kd. An additional component of suppression may be the lack of osmotic buffers provided by macromolecules. The third component of ultrafiltrate-mediated suppression is that of SIFs. One third of patients with cancer had suppressive serum. The ultrafiltrate of serum from these patients was suppressive in 78% of patients. The finding of suppressor activity in the ultrafiltrate of normal individuals with increased amounts in patients with cancer suggests that SIFs are normal serum constituents and are significantly increased in advanced cancer. They may be offset by simultaneous elaboration of enhancing factors, accounting for lesser suppression of blastogenesis by intact serum from patients with cancer compared with ultrafiltrate from these same patients.

Next, efforts were aimed at providing additional evidence to support the presence of SIFs. This was accomplished by diluting ultrafiltrate with tissue culture medium. The reversal of suppression of lymphocyte blastogenesis noted in ten of 14 samples after dilution further supported the presence of increased amounts of SIF rather than lack of lymphocyte-enhancing factors. The presence of SIFs was assured with the HPLC technique, which demonstrated increased levels of SIFs correlating closely with suppression in the blastogenesis assay. The ease and reliability of the HPLC method has supplanted the bioassay to detect SIFs in our laboratory.

The phase I trial of continuous plasma UF was successful in terms of feasibility and toxic effects. The UF controller we used functioned well, handled blood at adequate rates, and provided sufficient control over flow rates, transmembrane pressures, and line pressures to optimize plasma UF. Adequate safeguards were supplied in the form of automatic line clamps and bubble detectors. The filter (Diafilter 30) functioned well, without failure at transmembrane pressures as high as 350 mm Hg. The limiting factor in terms of UF rate was the lumen size of the dialysis catheter. With catheter-related problems representing the major obstacle to continuous UF, it is difficult to envision the use of larger catheters.

None of the six patients in the UF trial manifested significant clinical benefit from UF. Of the five patients with anergy before therapy, all were unresponsive to skin testing after treatment. When the analogy to the animal model is considered, this result is not unexpected. We currently view the suppressor effect of cancer serum as the net result of lack of enhancing factors combined with increased levels of SIFs. In the population studied, only SIFs would be expected to be present. The ability to remove SIFs by continuous UF was clearly demonstrated. What is likely required for successful immunotherapy with UF is earlier intervention when endogenous lymphokine levels remain high or the simultaneous administration of exogenous lymphokine.

Despite the vast increase in knowledge relating to cellular immunology, only recently have significant results been achieved with the use of biologic agents as cancer therapy.[13,14] Responses have been brief, occurring only in a small portion of patients. The general lack of benefit of biologic response modifiers may be a failure to address adequately the suppression side of the immune response to cancer. It is overly simplistic to view cancer-related immunosuppression solely as the result of the presence of low-molecular-weight SIFs. Yet, in our animal models, these factors appear to exert a major biologic influence. The use of continuous UF combined with interleukin 2 may augment response to interleukin 2 with lower doses and less toxic reaction. This combined approach, simultaneously removing suppressor molecules and adding enhancing factors, may be required for effective cancer immunotherapy.

I am grateful for the support of COBE Laboratories, Lakewood, Colo, and Amicon Corp, Danvers, Mass, for furnishing essential devices and supplies. I greatly appreciate the superb nursing assistance provided by Kelly Gullixson.

Discussion

Q Do you have any idea what these factors are? Have you done these studies on them?

A Yes and no. We have been working with the suppressor factors on a variety of different levels. We have extensively characterized these factors in the rat model, and a characterization actually appears in the *Journal of Oncology*.

Endoscopic Ablation of Esophageal Malignancies With the Neodymium-YAG Laser and Electrofulguration

Hector R. Nava, MD; Marlys E. Schuh, MD; Raman Nambisan, MD; John L. Clark, MD; Harold O. Douglass, Jr, MD

• The case reports of 40 patients with obstructive esophageal cancer treated with electrofulguration (EF) or neodymium (Nd)-YAG laser were reviewed. Surgery was contraindicated because of advanced carcinoma (17 patients), recurrence after resection (13 patients), recurrence after irradiation (four patients), and poor medical condition (four). Two patients refused surgery. There were 31 men and four women; mean age was 62 years. There were 31 adenocarcinomas, eight squamous cell carcinomas, and one metastatic breast carcinoma. Tumor locations were lower esophagus in 35 patients, middle esophagus in three, and cervical esophagus in two. Thirty-five patients had obstructions; two, bleeding, and three, both. None of the patients could swallow solids. A total of 255 treatments were given (mean, 6.6 per patient). The mean number of Nd-YAG treatments was 1.9; for EF, 1.3. All 40 patients tolerated solid food after treatment and the esophagus remained open from three to 14 weeks. Mean survival from first treatment was 11 months; from diagnosis, 17 months. Both techniques were safe and effective.

(*Arch Surg* 1989;149:225-228)

Since the five-year cure rate of esophageal carcinoma remains poor, palliation is often the main goal of treatment.[1] A number of modalities used in the past to achieve palliation resulted in varying degrees of efficacy. These include surgery, radiation therapy, dilatation, and intubation.[2-4] In recent years, however, endoscopic treatment of malignant esophageal obstructive lesions with the neodymium (Nd)-YAG laser has emerged as a promising therapeutic option.[5,6] This report is a retrospective review of the palliative treatment of esophageal carcinoma with endoscopic Nd-YAG laser and endoscopic monopolar electrofulguration (EF) in 40 patients treated at Roswell Park Memorial Institute, Buffalo, between May 1984 and December 1986.

Accepted for publication July 8, 1988.

PATIENTS AND METHODS

The case histories of 40 patients who were seen consecutively at Roswell Park Memorial Institute between May 1984 and December 1986, and were diagnosed as having carcinoma of the esophagus for which palliative therapy was administered were reviewed. Surgical treatment was contraindicated in these patients for the following reasons: the presence of advanced carcinoma at the time of diagnosis, 17 patients; recurrent carcinoma following resection, 13 patients; recurrent carcinoma following radiation therapy, four patients; and unsatisfactory medical condition, four patients. Two patients refused surgery. Adenocarcinoma of the esophagus was diagnosed in 31 patients; eight patients were found to have squamous cell carcinoma; and one patient had adenocarcinoma of the breast with metastasis to the esophagus. The mean age of the patients in this series was 62 years, with a range of 32 to 86 years.

Thirty-six of the patients were men; four were women. The majority of the malignant esophageal lesions (35 of 40) were located at or distal to 35 cm. In one patient, the lesion was present in the upper part of the esophagus at 19 cm from the incisors, and in the remaining four patients, the lesion was located in the middle of the esophagus at 22 to 34 cm.

Obstruction was the predominant presenting symptom in 35 patients. Acute bleeding was the reason for referral in two patients, and three patients reported symptoms of both obstruction and hemorrhage. The degree of esophageal obstruction was such that all 40 patients were unable to tolerate solid food. Obstructive dysphagia was severe enough in several patients to preclude even passage of saliva. Although a few patients in this series were able to swallow liquids, at the time treatment was administered none was capable of oral intake sufficient to maintain energy requirements.

TREATMENT TECHNIQUE

Endoscopic laser therapy was performed using an Nd-YAG laser (Medilas-2) with a power output calibrated to deliver 80 to 100 W. Laser energy was applied via quartz fibers placed through the operating channel of the fiberoptic endoscope (Pentax-FG 36TA), with a white ceramic tip adapted for the laser, or through the smaller-diameter fiberoptic endoscope (Pentax-FG 34JH). Laser energy was applied under direct vision in short pulses, visually regulated not to exceed 2 s. Treatment was performed in a retrograde fashion whenever possible, but due to the degree of

Fig 1.—Left, Adenocarcinoma with nearly complete obstruction. Notice dilatation proximal to tumor. Right, Eight weeks later, no tumor is seen in lumen: shouldering effect and proximal dilatation have disappeared. Arrows indicate location of tumor before and after electrofulguration.

Fig 2.—Left, Complete obstruction by adenocarcinoma. Right, Final result after several neodymium-YAG laser treatments; raggedy edges outline channel created. Percutaneous endoscopic gastrostomy tube has been placed for nutritional supplementation.

Fig 3.—Complete esophageal obstruction by adenocarcinoma. Lumen is not discernible at junction of folds.

Fig 4.—Circumferential necrosis of esophageal tumor after endoscopic electrofulguration. Monopolar electrocautery probe inside of stricture.

obstruction present, this could be accomplished only if esophageal dilatation was first performed with Savary or balloon dilators. Thus, most treatments were administered in an antegrade fashion with the laser directed at the obstructed lumen (Figs 1 and 2).

Endoscopic EF therapy was performed using a monopolar unit (Valleylab SSE2-K) with the electrode (ACMI ball-tip) placed through the operating channel of the fiberoptic endoscope (Pentax-FG 34JH). The power setting on this instrument was 80 W. Treatment was administered in a retrograde fashion whenever possible, but unlike the Nd-YAG laser, the smaller diameter of the electrocautery EF probe permitted passage distal to the strictured lumen (Figs 3 through 5).

In the earlier years of the period under review, most patients were treated by EF, with treatment using the Nd-YAG laser becoming more frequent in the later years of the study. It was observed that a number of patients underwent both therapeutic modalities during different treatment courses.

For each type of therapy, treatments were repeated at 48- to 72-hour intervals until luminal patency was sufficiently established to allow the passage of the 11-mm-diameter endoscope into the stomach and to allow oral intake of solid food. During the period under review, a total of 12 percutaneous endoscopic gastrostomy tubes and one nasogastric feeding tube were placed.

RESULTS

The 40 patients examined in this study received a total of 255 treatments. The average number of treatments per patient was 6.6 (range, one to 32 treatments). It was determined that it required an average of 1.8 treatments (range, one to six treatments) with the Nd-YAG laser to establish luminal patency as compared with 1.3 treatments (range, one to four treatments) when employing the electrocautery EF probe. This result was independent of whether or not the patient was receiving chemotherapy in addition to endoscopic therapy.

The duration of response was variable. It was found that courses of treatment to reestablish adequate luminal patency were required on average every four weeks. In several patients, re-treatment was necessary in as little as three weeks, whereas other patients did not develop severe

Fig 6.—Estimated survival time since diagnosis of 40 patients with esophageal malignant obstruction treated endoscopically.

Fig 7.—Estimated survival time since first endoscopic treatment.

obstruction for approximately eight to ten weeks.

Of the five patients with symptoms of hemorrhage, bleeding was controlled with EF in three of them. In the remaining two patients, hemostasis could not be achieved with either the Nd-YAG laser or EF. Angiographic embolization of the left gastric artery was attempted in both patients, but treatment was unsuccessful and these two patients subsequently died of exsanguination.

The median survival time in all 40 patients from the time of the first endoscopic treatment was 11 months. The estimated one-year survival was 40%. In this patient population, median survival time from diagnosis was 17 months, with an estimated one-year survival of 65% (Figs 6 and 7).

At the time this review was carried out, 24 patients had died. The cause of death was progressive metastatic disease in nine patients, respiratory failure (eg, tracheoesophageal fistula, from tumor breakdown, aspiration pneumonia, or tumor involvement) in five patients, bleeding in five patients, sepsis in three patients, and myocardial infarction in two patients.

COMPLICATIONS OF THERAPY

Transient febrile (temperature >38.5°C) episodes occurred in three patients. Blood cultures did not yield the causative organism and the fevers resolved without antibiotic therapy. Antibiotics were required to treat two patients who developed fever and had positive blood cultures (*Escherichia coli*) subsequent to endoscopic therapy. Both patients recovered without further sequelae. One patient with diffuse abdominal carcinomatosis developed abdominal distention and crampy pains following endoscopic treatment. This was attributed to air insufflation and resolved without other therapy. Significant posttreatment pain, requiring parenteral narcotics for several days, occurred in one patient.

In addition to the five patients treated initially for bleeding, another 13 patients developed acute or chronic bleeding during the treatment period. None of the patients whose tumors were located in the middle or upper parts of the esophagus experienced significant bleeding. Hemorrhage from the tumor in the distal part of the esophagus appeared to increase in frequency and severity with repeated treatment courses, with most bleeding occurring as chronic oozing from the tumor surface. Several patients, however, developed acute massive bleeding. In one patient, angiographic embolization of the left gastric artery was successfully carried out. In the other patients, hemostasis was achieved endoscopically. Exsanguination was a direct cause of death in five patients. Hemorrhage seemed to occur with equal frequency whether treatment was performed with the laser or EF. However, all patients with massive hemorrhage were treated using the Nd-YAG laser.

COMMENT

It was found that endoscopic treatment with either the Nd-YAG laser or monopolar EF was well tolerated by all the patients in this series. No esophageal perforations or cases of aspiration pneumonia attributable to treatment were encountered. Treatment resulted in some transient febrile episodes (2%), with occasional bacteremia requiring antibiotic therapy (0.8%).

Symptomatic relief of the mechanical obstruction was achieved in all 40 patients, since ability to tolerate solid food was improved after treatment. Despite this, it was observed that in a number of patients, energy intake did not improve significantly after treatment. Whenever possible and acceptable to the patient, placement of a percutaneous endoscopic gastrostomy tube was carried out to enhance the nutritional status of these anorexic patients. It was also found that opening the percutaneous endoscopic gastrostomy tube during treatment aided in smoke evacuation and prevented any gastric dilatation as a result of insufflation.

It appeared that extensive tumor involvement with vascular encasement occurred in patients having the type of malignant stricture evaluated in this study. Endoscopic treatment with either the Nd-YAG laser or EF resulted in tumor ablation, with erosion of the involved vessels. Although the small bleeding points could be readily controlled endoscopically, as larger vessels were encountered, the resulting hemorrhage could become massive and life threatening.

Aspiration pneumonia and malnutrition are generally considered to be the usual causes of death from esophageal carcinoma. However, this was not true for the patients in this series. Aspiration pneumonia accounted for only one death. Progressive metastatic disease (particularly pul-

monary and hepatic) and bleeding were the most frequently encountered causes of death.

The results presented herein appear to indicate that EF was capable of establishing luminal patency earlier than was therapy using the Nd-YAG laser. An average of 1.3 treatments with EF were required vs 1.8 treatments with the Nd-YAG laser, to establish the esophageal lumen. One possible explanation for this result is that the EF electrode is only 2 mm in diameter and can be passed for a greater distance distally into the malignant stricture. Therapy is thus administered in a retrograde fashion as the electrode is withdrawn, thus permitting treatment of a longer segment of the tumor. With the Nd-YAG laser, the lumen becomes increasingly difficult to discern, because of the presence of charring that develops along the walls of the treated area. Passing a probe to help visualize the lumen is not always effective. It must be pointed out that since this was not a randomized prospective study, exact luminal measurements before and after treatment were not available. Therefore, differences in treatment efficacy between the Nd-YAG laser and EF must be interpreted in that context.

The survival data in this series indicate that adequate palliation was maintained for prolonged periods. Because the duration of palliation following treatment varies considerably (ranging from three to 14 weeks), re-treatment is often required and may be performed as indicated, since no maximum dose has been established. A program of re-treatment before the esophageal lumen becomes completely obstructed would be desirable, since treatment is much less difficult with a well-defined esophageal lumen.

Endoscopic therapy with either EF or the Nd-YAG laser does not preclude treatment with other modalities. In the present study, more than half the patients examined also received chemotherapy. No problems were encountered coordinating the two forms of treatment.

Considerable differences exist in availability and cost of equipment between monopolar EF and Nd-YAG laser therapy. In this study, the superiority of the Nd-YAG laser over the more conventional form of therapy (EF) was not demonstrated. It should be emphasized that this was a retrospective review, rather than a controlled, randomized study. However, in view of the equivocal data available to date and given the cost factors involved, we would recommend that a randomized, controlled study be carried out as soon as possible to objectively evaluate these two modalities in the palliative treatment of malignant stricture resulting from the presence of esophageal carcinoma.

Discussion

Q What specific laser settings did you use?

A In reference to the YAG laser, the laser was set between 60 and 100 W. I usually prefer to use maximum power; the higher the power, the quicker the effect, and the less the penetration; this has been documented by others as the better way to use the laser.

Q What was the origin of the bleeding?

A In two patients the origin of the bleeding was documented arising in branches of the left gastric artery. Both of those patients had adenocarcinomas of the gastroesophageal junction and they did not bleed at the time of treatment. Subsequently, they experienced massive bleeding and it was very hard to determine whether it was the effect of the laser or just the natural course of the disease.

Q Can you use these techniques on benign structures?

A Actually, what prompted us to use these techniques, especially electrocautery, were reports from Germany using monopolar electrocautery to open benign postsurgical strictures. Definitely, both techniques can be used for benign strictures and we have done so on patients who developed benign strictures following esophagogastrectomies.

Q Did it work?

A Very well.

Q How about the contact laser?

A We had tried the contact laser with tips. The advantage of the contact method is that it reduces the depth of penetration of the laser; however, because of that it takes more time to debulk large amounts of tumor.

Q Which of the techniques is the best?

A Obviously a prospective randomized study needs to be done, not only between these two techniques, but with photodynamic therapy, bipolar therapy, and the heater probe, which are also techniques reported as being useful in this type of problem. We have continued to accumulate experience with the YAG laser. Since we have a lot of experience with monopolar EF, we are now in a position where we should be able to run a prospective randomized study between these two techniques. The recommendation to the group is that if the YAG laser is available it is perhaps the treatment of choice as long as there is someone who can use it. But, if it is not available, then you have the alternative, less expensive, form of therapy, which is monopolar EF.

Are Complications in Intraoperative Radiation Therapy More Frequent Than in Conventional Treatment?

Douglas T. Cromack, MD; Michelle M. Maher, RN; Harald Hoekstra, MD, PhD; Timothy J. Kinsella, MD; William F. Sindelar, MD, PhD

• To evaluate whether intraoperative radiation therapy (IORT) results in higher complication rates than conventional radiotherapy, 119 patients were studied who entered four prospectively randomized clinical trials that compared IORT with conventional therapy. Malignant neoplasms included 33 gastric carcinomas, 35 retroperitoneal sarcomas, 22 resectable pancreatic cancers, and 29 unresectable pancreatic cancers. One hundred thirty-six complications developed among 66 patients who received conventional therapy, and 108 complications developed among 53 patients who received IORT. There was no statistical significance between treatment groups with respect to the overall incidence of complications. Analysis of types of complications by tumor type using Fisher's exact test revealed only one significant complication: an increased rate of sepsis among the patients with retroperitoneal sarcoma who received conventional therapy compared with their IORT cohorts. The overall complication rate associated with IORT was equivalent to conventional radiotherapy in the treatment of these malignant neoplasms and supported the use of IORT where clinically indicated.

(*Arch Surg* 1989;124:229-234)

Achieving local and regional control of many intra-abdominal malignant neoplasms remains a difficult and unrewarding task for the surgical oncologist despite the current availability and use of multimodality therapy. During the past decade, increasing enthusiasm for the use of intraoperative radiation therapy (IORT) has developed in some oncology centers.[1] Intraoperative radiation therapy allows the delivery of a single radiation dose directly to a tumor mass or to a resected tumor bed during a surgical procedure. Intraoperative radiation therapy potentially spares normal tissue in the vicinity of the treatment volume by operative displacement of tissues out of the treatment field. Intraoperative radiation therapy allows the delivery of large tumoricidal radiation doses to a malignant neoplasm with a low risk of radiation damage to normal tissues.

While complications associated with the use of IORT have been recognized, there have been no systematic reports comparing the types of IORT-related complications, their frequency, and their time course with the types of complications associated with conventional external-beam radiation therapy. In light of the theoretical treatment advantages of IORT in cancer therapy, objective analyses of the complications associated with the use of IORT are needed. For several years, the National Cancer Institute (NCI) has conducted randomized trials evaluating surgery in combination with IORT compared with surgery in combination with conventional radiotherapy for the treatment of retroperitoneal sarcomas, gastric adenocarcinomas, and both resected and unresected pancreatic cancers.[1-4] These trials have suggested a benefit in local disease control but not in overall survival. The trials have not yet, however, sufficiently matured to draw firm conclusions on the efficacy of IORT compared with conventional radiotherapy. The present study analyzes both IORT and control groups to address whether the complications of IORT differ from those of conventional treatment.

PATIENTS AND METHODS

Patients and Characteristics

The clinical courses of 119 patients were analyzed for complications secondary to therapy, representing all patients who were prospectively randomized to approved NCI treatment protocols that involved retroperitoneal sarcomas, gastric cancers, or pancreatic cancers. In all protocols, patients received either surgery with IORT or surgery with conventional radiotherapy (Table 1). The IORT and control patient populations had similar surgical procedures performed and were comparable with respect to sex, age, and disease state (Table 2). Three reviewers classified every clinical complication in each patient as to the probable underlying cause: radiation therapy (IORT or conventional), surgery, chemo-

therapy, progressive malignant neoplasm, or other factors. The complications due to surgery or radiation therapy are considered in this analysis. Complications were graded by type, severity, frequency, and chronologic occurrence. Every complication episode was recorded throughout the entire clinical course of every patient, so that some patients were scored as having multiple episodes of the same type of complication. Twenty-nine separate types of complications were identified within seven general categories: gastrointestinal, urologic, vascular, neurologic, cardiorespiratory, infectious, and miscellaneous (Table 3). Early complications were defined as those that occurred within 30 days of surgery. Late complications were defined as those that occurred more than 30 days after surgery. Complications that resolved spontaneously or with little medical intervention were assessed as minor. Complications that required active therapy, invasive intervention, or surgery, and those that were life threatening were considered major. Treatment-related mortality was defined as any death that occurred within 65 days of surgery during the initial hospital admission. The lengths of the hospital stays that were required due to primary treatment and radiation-related complications were recorded for all patients, and the percentage of overall survival time spent in the hospital was calculated.

Statistical Methods

Statistical analysis by the χ^2 test was used to compare IORT and control patient populations for the frequency of complications, the overall incidence of complications, treatment-related mortality, and the frequency and incidence of specific types of complications. Fisher's exact test was utilized to compare the incidence of early and late complications and to evaluate complication subgroups by tumor type and method of radiation. Student's t test was used to compare the frequency of complications per patient among the various tumor types and treatment arms. Hospitalization durations were compared using the Wilcoxon rank-sum test.

RESULTS

Patient Groups

One hundred nineteen patients in four randomized studies at the NCI were evaluated for complications that resulted from therapy. Sixty-six patients received conventional therapy and were considered to form the control group. Fifty-three patients received IORT and constituted the experimental group. Tumor types and the distribution of disease stages were similar (Table 2). The median follow-up time was 53 months for the control group and 54 months for the experimental group.

Incidence of Complications

A total of 136 complications developed among 66 patients who received conventional therapy, and 108 complications developed among 53 patients who received IORT (Table 3). No statistically significant differences were present between the control and IORT groups with respect to the overall incidence of complications. No differences in complication incidence were present when each specific tumor type was analyzed independently.

The majority of complications occurred within the gastrointestinal category and included enteritis, bowel obstruction, and hemorrhage (Table 3). Analysis within the

categories of gastrointestinal, urologic, vascular, neurologic, cardiorespiratory, infectious, and miscellaneous revealed no overall differences in the incidence of complications between the control and IORT patient groups (Table 3 and Figure). However, analysis of complications within each tumor type revealed one area of significant difference (Figure): There was a greater incidence of sepsis among patients with retroperitoneal sarcomas who received conventional therapy compared with patients with retroperitoneal sarcoma patients who received IORT.

Complication Episodes

Nine patients (17%) who received IORT and 15 patients (23%) who received conventional therapy had no compli-

Incidence is reported as percentage of patients developing indicated complication in each tumor type. Statistical comparison of controls and patients who received intraoperative radiation therapy (IORT) by Fisher's exact test is shown. Significant values ($P<.05$) are indicated by asterisk. GI denotes gastrointestinal.

cation episodes at any time, while 44 IORT patients and 51 control patients suffered one or more complication episodes after therapy. The maximum episodes in a single patient was 17 for the control group and 12 for the IORT cohort. Repeated episodes of intra-abdominal or gastrointestinal bleeding and life-threatening sepsis in the immediate postoperative period accounted for more than 50% of the complication episodes, resulting in 54 operative interventions for the treatment of complications and, ultimately, in ten of the 11 postoperative deaths.

Comparison of IORT and control patient groups revealed no significant differences in the overall numbers of complication episodes and no differences in the numbers of episodes grouped according to complication category. Analysis by tumor type revealed no area of significant difference between IORT and control patients.

Mortality

Overall treatment-related mortality among the treatment groups and tumor types did not differ significantly. There were five deaths among the control patients and seven deaths among the IORT patients (Table 4).

Early and Late Complications

Early and late complications occurred in similar overall frequency in both the IORT and control treatment groups. Early complications comprised 58% of the total control group complication episodes and 47% for the IORT group episodes. Late complications comprised 42% of all control group complication episodes and 53% of all IORT episodes.

Table 4.—Mortality by Treatment Group and Tumor Type*

Tumor Type	Pancreas Resected	Retroperitoneal Sarcoma	Gastric Carcinoma	Pancreas Unresected	Total	P
Control	1	2	0	2	5	NS
IORT	4	1	1	1	7	NS

*NS indicates not significant; IORT, intraoperative radiation therapy

Table 5.—Proportion of Overall Survival Time Spent in Hospital*

Overall Survival Time, mo	Overall Survival, %		
	Control	IORT	P
<6	15.4	39.7	NS
6-12	16.7	24.5	NS
12-24	10.7	13.8	NS
>24	5.5	4.8	NS
Total	11.0	17.7	NS

*Postoperative deaths are excluded. IORT indicates intraoperative radiation therapy; NS, not significant.

Hospitalization due to Complications

The total durations of hospitalization time due to complications or related treatment were similar for both IORT and control treatments, as measured by the percentage of time spent in the hospital adjusted for overall survival (Table 5). Hospitalization time for all control patients averaged 11% of overall survival and averaged 18% for IORT patients.

COMMENT

Intraoperative radiation therapy, while first utilized as early as 1909, gained increased acceptance during the late 1970s after the development of high-energy linear accelerators and initial clinical trials.[1,5] Presently, IORT remains an experimental therapy utilized at several cancer centers to achieve local-regional control of various intra-abdominal malignant neoplasms. Limited information is available for an accurate assessment of the risk of complications due to IORT. Published results of IORT trials have recognized certain treatment-related complications. A report from the Massachusetts General Hospital, Boston, compared historical controls who had colorectal cancer with IORT-treated patients and found no increase in complication rates resulting from the experimental therapy.[6] However, no prospective comparisons of complications between conventional radiotherapy and IORT have been published.

The IORT-related complications recognized by previous authors have included gastrointestinal bleeding,[7,8] intestinal obstruction,[9] infectious complications,[10] and peripheral neuropathies.[11] Similar types of complications occurred in the prospective randomized NCI trials, reviewed here, that compared IORT with conventional radiotherapy in the treatment of retroperitoneal sarcomas, gastric adenocarcinomas, and resected and unresected pancreatic cancers. Importantly, no significant differences in complication rates emerged between IORT and control groups when analyzed by type of radiation therapy, functional category, or type of tumor. Consequently, an equivalent complication risk exists between IORT and conventional radiotherapy in the treatment of intra-abdominal malignant neoplasms. Oncologists can recommend experimental IORT when clinically indicated without subjecting patients to an increased risk of complication, compared with conventional radiotherapy.

Early in the development of IORT, there were theoretical concerns of the possibility of increased infectious complications in IORT due to technical manipulations (transportation of patients under anesthesia between operating and radiotherapy suites) and the temporary placement of foreign bodies within the abdominal cavity (IORT applicators, shielding, and tissue retractors). Such concerns have been proved to be unfounded based on the data in the current study. The incidence of infectious complications was similar in both IORT and conventional radiotherapy groups. Separate analysis by tumor type actually revealed an excess of infectious complications among the conventional-treated patients with retroperitoneal sarcomas.

Analysis of specific tumor types revealed findings that appeared to correlate with previously described IORT-associated complications. Kinsella et al[11] reported late-appearing peripheral neuropathies both in an experimental IORT model in dogs and in patients who received IORT for retroperitoneal or pelvic tumors. While the current results failed to show a statistically significant overall difference between conventional radiotherapy and IORT, there was a tendency toward increased late peripheral neuropathies in patients with retroperitoneal sarcomas who received IORT. As was demonstrated in experimental animal models, IORT applied to the area of lumbar or sacral plexus can produce demyelination and peripheral neuropathy, a phenomenon that was dose related.[11] Limited patient survival due to tumor recurrence may have prevented the appearance of a higher rate of late peripheral neuropathy among the patient group with retroperitoneal sarcomas at the NCI.

Upper gastrointestinal tract bleeding associated with IORT for pancreatic cancers has been reported.[7] Current NCI results have demonstrated a tendency toward an increased gastrointestinal bleeding after IORT in patients with unresectable pancreatic carcinoma. Hemorrhage typically occurred four to six months after treatment and was due to ischemic necrosis of the mucosa on the medial duodenal wall, an area routinely included in IORT portals to encompass tumor masses in the head of the pancreas.[8,12] In all patients who experienced duodenal hemorrhage, the bleeding episodes were self-limiting and ceased after the denuded duodenal wall healed with scar formation six or more months after therapy. This complication may be an expected complication of IORT applied to unresected pancreatic cancer and appears to occur in 20% to 30% of treated patients who survive six or more months.

Enteritis and associated bowel obstruction are recognized complications of wide-field, high-dose, external-beam abdominal radiation therapy, occurring in up to 25% of patients.[13] A theoretical advantage to IORT is a lessening of intestinal exposure to radiation dose and a consequent reduction of the risk of late radiation-related enteritis and associated bowel obstruction. This theoretical advantage for IORT may be validated by the current study, since a lower incidence of enteritis was observed in those patients who received IORT for resected pancreatic cancer and for

gastric carcinoma (both trends bordering on significance).

Intraoperative radiation therapy did not increase the overall risk of complications or overall mortality among patients in the NCI prospectively randomized trials. Therefore, it appears that IORT can be used for treatment, where clinically indicated, without exposing patients to an increased risk of treatment-related complications. The small number of patients and the high overall complication rate could mask small differences between control and experimental groups. Comparison of radiated and nonradiated patients in a prospective trial would be of interest in determining the risk added to surgery by radiotherapy in general.

Although IORT may increase the risk of duodenal hemorrhage and peripheral neuropathy in certain circumstances, IORT does appear to enable the delivery of high radiation doses to large abdominal fields with a lower incidence of long-term intestinal complications. This report of complications developing during randomized clinical trials demonstrates the relative safety of IORT and supports continued investigation into its clinical role as a cancer treament.

The authors thank Seth Steinberg, PhD, Rosalie Smith, RN, and Donald White, MS, for their help in the preparation of this manuscript.

Discussion

Q I recently reviewed the series of the radiation therapy oncology group. We have almost 200 cases, and our data are very similar to what you presented with regard to the complication rate. Most of the institutions that are participating are transporting patients. I know you transported patients early on in your studies. How many of your patients were transferred vs how many were treated in your dedicated unit?

A The breakdown is approximately 40% of patients were transported, and approximately 55% to 60% of patients were treated in the dedicated unit. We found that the actual incidence of complications, which were all wound infections, between the two groups were virtually identical. We are not sure whether we can attribute that to the transport problem or just to the overall technique and attention to detail.

Q Are there ongoing controlled trials of IORT? Can you separate radiation from surgical complications?

A Initially, there were four separate clinical trials, looking at IORT vs the external-beam radiation therapy arm. Several of the trials are ongoing and continue to accumulate patients. Regarding the second point of your question, we felt that it would be very difficult to try to distinguish between those complications that were solely related to the surgical treatment and those related to radiation. Some would be very easy to break out, and some were in the overlap area. We felt that since radiation therapy, given at the time of surgery, involves additional manipulation of the surgically exposed tumors, we should examine the complications of both the surgery and the radiation treatment. As far as the overall incidence of complications, as compared with that reported in the literature, again we tried to be very meticulous about those complications that we classified as complications vs what we would routinely expect in a normal patient. I believe our data correlate well with other reported literature, as far as the incidence of complications in treated patients who did not receive radiation therapy.

ARCHIVES OF PATHOLOGY & LABORATORY MEDICINE

Juvenile Granulosa Cell Tumor of the Testis

Manuel Nistal, MD; Elena Redondo, MD; Ricardo Paniagua, PhD

Juvenile granulosa cell tumor occurred in a newborn. The tumor presented with testicular torsion, and no malformations were observed. The karyotype was normal. The occurrence of initial tumoral lesions in the seminiferous tubules located in the vicinity of the tumor suggests that the tumor originated from immature Sertoli's cells. To our knowledge, this is the tenth case reported in a newborn and the second associated with testicular torsion (*Arch Pathol Lab Med* 1988;112:1129-1132).

The Influence of Natural Killer Cells in Neuroblastoma

John V. Reynolds, FRCS(I); Jian Shou, MD; Hoon Choi, MD; Robert Sigal, MD; Moritz M. Ziegler, MD; John M. Daly, MD

• Human neuroblastoma (NRB) cell lines are markedly sensitive to natural killer (NK) cell lysis in vitro, but patients with NRBs have low or absent NK activity. This study evaluated the NK sensitivity of murine NRBs (C1300 and TBJ) in the regulation of NRB growth and determined the effects of recombinant (r) interferon gamma and recombinant interleukin 2 (rIL-2). Both basal (8%±3% specific cytotoxicity) and induced (20%±3%) NK lyses of C1300-NRB were observed. In vivo depletion of NK cells with anti–asialo GM-1 significantly enhanced growth of C1300-NRB and deceased survival. Treatment wth r–interferon gamma or rIL-2 on days 1 through 3 after C1300-NRB inoculation significantly prolonged the mean tumor latency period, decreased the tumor growth rate, and enhanced in vitro NK killing of C1300-NRB and YAC-1. The effects of r–interferon gamma and IL-2 were abrogated by pretreatment with anti–asialo GM-1. These results demonstrated that NK cells form one important component of regulation of a murine NRB, but immunomodulation with potent lymphokines requires cooperation of more than one cell type.
(*Arch Surg* 1989;124:235-239)

Neuroblastoma (NRB), first described by Virchow[1] in 1865, represents the most common extracranial solid tumor seen in childhood. Despite multimodality therapy, including surgery, radiotherapy, chemotherapy, and bone marrow transplantation, the overall three-year survival remains at 35%.[2]

Neuroblastoma may be influenced by immunologic mechanisms since spontaneous regression of tumor has been observed.[3-5] Cytotoxic lymphocytes, humoral responses, and tumor-induced "blocking" antibodies have also been demonstrated in patients with NRB, although their prognostic significance is unclear.[6]

Recently, Lampson et al[7] and Main et al[8] characterized human NRB cell lines in terms of both HLA-A, HLA-B, and HLA-C (class 1 major histocompatibility complex [MHC]–encoded antigens) expression and sensitivity to cytotoxic effector mechanisms. Human NRB cell lines lack significant class 1 antigens, but these can be readily induced by interferon gamma.[9] This implies that class 1 MHC-restricted cytotoxic T-cell (CTL) killing of NRB is unlikely to be significant in vivo unless class 1 antigens are upregulated by endogenous or exogenous interferon gamma. Immunologic manipulation, based on upregulating natural killer (NK) function, modulating class 1 MHC expression, or combinations of both, may have therapeutic application. Recombinant interleukin 2 (rIL-2) and recombinant (r) interferon gamma are potent activators of NK cells that have the capacity to modulate class 1 expression.[10-12]

Natural killer cells represent a subpopulation of lymphocytes that mediate non-MHC-restricted killing of certain target and tumor cells.[13,14] Natural killer cells have been demonstrated to modulate the development of primary tumors and to control the development of metastases.[15,16] Phenotypically, NK cells are Thy-1.2⁻ and Lyt-2⁻ but express the surface antigen, asialo GM-1.[17] The CTLs are phenotypically Thy-1.2⁺ and Lyt-2⁺ and may express asialo GM-1 to a variable degree.[18] In vivo depletion of NK cells by treatment with antiserum to asialo GM-1 has been demonstrated to facilitate local tumor growth and metastases.[19,20]

This study was designed to determine whether NK cells have a regulatory role in murine NRBs. Both in vivo depletion and in vivo activation experimental regimens were used to modulate NK function at a period when NK resistance to tumor growth might be most critical.[21] The overall objective of the study was to determine whether a suitable animal model of NRB exists, comparable with human NRB, so that immunotherapeutic modalities of treatment with potential clinical application may be fully evaluated.

MATERIALS AND METHODS

Mice

Six-week-old male A/J (H-2^a), CBA/J (H-2^h), CFW (H-2^k), and DBA/2 (H-2^d) strain mice were obtained from the Jackson Laboratory, Bar Harbor, Me.

Tumors

The C1300-NRB arose from the spinal cord region of A strain mice in 1940, and it has been maintained by serial in vivo and in vitro passage ever since. The TBJ-NRB is a clonal variant of C1300-NRB with markedly reduced immunogenicity. The antigenic characteristics of both tumors have been previously described.[22] The P815, syngeneic to strain DBA/2, and the YAC-1 lymphoma of A/Sn origin were maintained in continuous in vitro culture.

Medium

Unless otherwise stated, all assays were performed in complete medium (CM), which consisted of RPMI 1640 supplemented with 10% heat-inactivated fetal calf serum, antibiotics (100 mg/L of penicillin and 100 U/mL of streptomycin), 2-mmol/L L-glutamine, and 5×10^{-5} 2-mercaptoethanol.

Reagents

Human rIL-2 was generously provided by a commercial manufacturer (Hoffmann-LaRoche Inc, Nutley, NJ). Murine interferon gamma was used. Polyriboinosinic:polyribocytidylic acid (Poly IC) was purchased commercially (Sigma Chemical Co, St Louis).

Preparation of Single Cell Suspensions

Single cell suspensions of spleen were prepared by mechanical disruption, followed by filtration through nylon mesh (Nytex, Tetko, Elmsford, NY). Cells were washed twice in RPMI 1640 and resuspended in CM.

Cytotoxicity Assays

Cytotoxicity to tumor targets was assessed using chromium 51–release assays. Labeling was performed by incubation of a $\times10^7$ viable target (C1300, TBJ, YAC, and P815) cells with 150-μL of sodium chromate 51 (2 mCi/mL, New England Nuclear, Boston) for 90 minutes. The assay was performed in V-bottomed microwells by adding serial dilutions of effector cells to 1×10^4 ^{51}Cr-labeled target cells in a total volume of 200-μL CM. The plates were centrifuged (800 revolutions per minute for five minutes) at the beginning of the assay, incubated at 37°C for four or 18 hours, and centrifuged again (1200 revolutions per minute for ten minutes). A volume of 100 μL was removed from each well for gamma counting. Percent-specific ^{51}Cr release was computed according to the following formula: $(E-S)/(M-S)\times100\%$, where E is the ^{51}Cr release in the presence of effector cells, S is the spontaneous ^{51}Cr release in the presence of the medium, and M is the maximum

Accepted for publication Oct 12, 1988.

Fig 1.—Ability of strain CBA/J spleen cells to lyse C1300-neuroblastoma (NRB), TBJ-NRB, and YAC-1 in standard four-hour chromium 51–release assay using either fresh spleen cells or spleen cells from mice injected with polyriboinosinic:polyribocytidylic acid (Poly IC) (100 μg intraperitoneally) 16 to 24 hours previously. Results represent mean of eight experiments; SDs ranged from 2% to 5%. NK indicates natural killer.

release obtained by the addition of the targets to an equal volume of 1% Triton X-100. The results are expressed as the mean percent lysis of triplicate experiments.

Generation of Lymphokine-Activated Killer (LAK) Cells

The LAK cells were prepared by incubating erythrocyte-free spleen cells at a concentration of 5×10^6/mL in 8-mL CM that contained 200 U/mL of rIL-2 in 25-cm³ tissue culture flasks. After three days of incubation at 37°C with 5% carbon dioxide, cells were harvested and were tested for lytic activity against P815, YAC, and C1300-NRB in four-hour ^{51}Cr-release assays as described above.

Generation of Allogeneic CTL

The CTLs were generated by coincubating responder strain A/J splenocytes (4×10^6/mL) with x-irradiated (20 Gy) strain DBA/2 stimulator spleen cells (2×10^6/mL) in a total volume of 8 mL. The resultant CTLs were tested against P815 in a four-hour ^{51}Cr-release assay as described above.

In Vivo Treatment With Monoclonal Antibodies or Antiserum

Anti–asialo GM-1 (Wako Chemicals, Dallas) was diluted 1/20 in phosphate-buffered saline (PBS) and filtered through a 0.22 μm filter (Millipore) (0.22 μm) before intravenous (IV) injection (0.4 mL per mouse). Injection of pooled normal rat serum served as a control. Purified anti–Lyt-2 (derived from hybridoma 2.43) was obtained commercially (Becton Dickinson, Sunnyvale, Calif), and 50 μg was injected IV in a total volume of 0.4 mL. Injection of rat IgG served as a control. These doses of antibody have previously been demonstrated to deplete specific target cells in vivo.[23,24]

Fluoresence-Activated Cell Sorter Analysis

The fluorescein isothiocyanate (FITC)–labeled anti–Lyt-2 and phycoerythrocin-labeled anti-L3T4 were purchased commercially (Becton Dickinson). The corresponding second reagent to anti–asialo GM-1, FITC goat anti–rabbit IgG (ab')2, was a gift. For staining, 10^6 cells were incubated with an appropriate concentration of primary antibody diluted in PBS that contained 2% fetal bovine serum and 0.1% sodium azide for 45 minutes at 4°C. They were then washed thoroughly and incubated with an excess of FITC-labeled second antibody for 30 minutes. Analysis of 50 000 cells per sample was performed on fluorescence-activated cell sorter microfluorometer (Ortho Cytofluorograf, Ortho Diagnostic Systems Inc, Raritan, NJ).

Experimental Protocol

Tumor (C1300-NRB or TBJ-NRB) was injected subcutaneously (1×10^6) on day 0. For in vivo depletion, ASGM-1 or Lyt-2 was injected on day 1 (in some experiments, injections were repeated every five days). On days 1 through 3, mice received rIL-2 (10^5 U intraperitoneally [ip] three times per day), r–interferon gamma (10^5 U/ip), Poly IC (100 μg ip), or PBS; all injections were administered in a total volume of 0.4 mL. The tumor incidence and latency period were recorded, and the tumor volume (major axis × minor axis) was measured every three days. On day 21, mice were killed by carbon dioxide insufflation, and the tumor weight was measured. In representative mice in each group, the liver and lung were examined for metastases as described by Wexler.[25]

Statistics

Statistical significance was determined by a two-tailed Student's *t* test.

RESULTS

Susceptibility to Lysis by NK Cells

As shown in Fig 1, the sensitivity of C1300-NRB, TBJ-NRB, and YAC-1 (positive control) to lysis by fresh and Poly IC (100 μg ip, 16 to 24 hours before the mice were killed) induced spleen cells from a number of strains of mice was determined. Natural cytotoxicity was manifest against C1300-NRB, which was enhanced with Poly IC pretreatment. However, no cytotoxicity, basal or induced, was manifest against TBJ-NRB.

Efficacy of In Vivo Depletion of NK (Anti–Asialo GM-1) and CTL (Lyt-2) Cells

Strain A mice (n = 6 per group) were injected IV with anti–asialo GM-1, anti–Lyt-2, or control normal rabbit serum and rat IgG, respectively. Three days after injection, fresh spleen cells were phenotypically analyzed for Thy-1.2, L3T4, Lyt-2, and asialo GM-1 and assessed for NK activity, CTL activity, and the potential to generate LAK cells. As shown in Table 1, anti–asialo GM-1 treatment markedly abrogated NK killing and significantly reduced LAK generation but did not alter CTL development. Anti–Lyt-2 treatment did not affect NK or LAK mechanisms but significantly decreased CTL development.

Effect of In Vivo Depletion of NK Cells or CTLs

Mice were pretreated before tumor inoculation (10^6 cells subcutaneously), and depletion was maintained by repeated IV injections (anti–asialo GM-1 every five days and anti–Lyt-2 every seven days). As shown in Table 2, in mice bearing C1300-NRB, the mean tumor weight was significantly ($P < .001$) increased by in vivo depletion with either anti–asialo GM-1 or anti–Lyt-2, compared with controls. The percentage mortality by day 21 was 4.5% for control mice, 45% for anti–asialo GM-1–treated mice, and 37.5% for anti–Lyt-2–treated mice. The effects of in vivo depletion with these antibodies in mice bearing TBJ-NRB were less

Table 1.—Anti–Asialo GM-1 and Anti–Lyt-2 Treatment Efficacy*

Treatment	Lysis (Effector-Target Ratio 100:1)			Spleen Cell Phenotype		
	NK† Cells	LAK‡ Cells	CTLs§	Thy-1.2‖ Cells	Anti–Asialo GM-1‖ Cells	Lyt-2‖ Cells
NRS¶	12	68	52	53	9.7	17.3
Anti–Asialo GM-1¶	0	29	50	51	2.5	15.5
Anti–Lyt-2¶	10	63	24	53	8.7	5.1

*Data represents the mean of three separate experiments; SD range, 2% to 10%. NK indicates natural killer; LAK, lymphokine-activated killer; CTLs, cytotoxic T lymphocytes; and NRS, normal rabbit serum.

†Percent lysis of YAC-1 by fresh spleen cells in a four-hour chromium 51–release assay.

‡LAK cells were generated by three-day culture in complete medium containing 200 U/mL of recombinant interleukin 2, and cytotoxicity to P815 was determined in a four-hour ^{51}Cr-release assay.

§CTLs were generated by coincubation of spleen cells from treated animals with x-irradiated DBA/2 spleen cells for five days, and cytotoxicity was determined in a four-hour chromium 51–release assay.

‖Percentage-positive antibody staining determined by fluorescein isothiocyanate–indirect immunofluorescence and quantitated by fluorescence-activated cell sorter analysis.

¶Anti–asialo GM-1 (0.4 mL) (diluted 1:20), anti–Lyt-2 (50 μg), or normal rabbit serum was injected intravenously in strain A/J mice (n = 8 per group), and assays were performed three days after the injection.

Table 2.—Incidence, Mortality, and Tumor WT Effects on Day 21 in Mice Bearing C1300-NRB and TBJ-NRB*

	C1300-NRB			TBJ-NRB		
	Incidence	Mortality	Tumor WT	Incidence	Mortality	Tumor WT
NRS†	22/22	1/22	2.4 ± 1.3‡	12/12	6/12	4.2 ± 1.3
Anti–asialo GM-1†	22/22	10/22	4.8 ± 0.9	12/12	7/12	4.9 ± 1.6
Anti–Lyt-2†	16/16	6/16	4.0 ± 0.2	12/12	7/12	4.8 ± 0.6

*NRB indicates neuroblastoma; WT, weight; and NRS, normal rabbit serum. Weight is given in grams as mean ± SD.

†Anti–asialo GM-1, anti–Lyt-1, anti–Lyt-2, or NRS was injected (0.4 mL) before tumor inoculation and repeated every five days (anti–asialo GM-1 and NRS) and every seven days (anti–Lyt-2).

‡$P < .001$, compared with both treatment groups.

dramatic, with a 14% increase in tumor weight in both treatment groups observed on day 21.

Efficacy of In Vivo Activation of NK With rIL-2 and Recombinant (r)–Interferon Gamma

Mice (strains CFW and A/J, n = 6 per group) were treated for three days with PBS (control), rIL-2 (10^5 U three times per day), or r–interferon gamma (10^5 U daily). On day 4, cytotoxicity of fresh spleen cells was tested against YAC-1, C1300-NRB, and P815 (NK-insensitive but LAK-sensitive control). As shown in Fig 2, the enhanced cytotoxic effect was more marked in rIL-2–treated mice than with r–interferon gamma treatment. These results were similar using YAC-1. No lysis of P815 was observed in any group. Basal NK killing was greater in strain CFW mice than in strain A/J mice, but r–interferon gamma– and rIL-2–induced killing was comparable in both groups (data not shown).

Antitumor Effect of rIL-2 and r–Interferon Gamma

The strain A/J mice (n = 10 per group) were injected with 10^6 cells subcutaneously on day 0 and received either PBS, r–interferon gamma, or rIL-2 from days 1 through 3. As shown in Fig 3, the tumor incidence on day 21 decreased from 100% in control mice to 80% in rIL-2–treated mice and to 50% in mice treated with r–interferon gamma. The mean latency period increased from seven days in control mice to 11 days in rIL-2–treated mice and to 14 days in r–interferon gamma–treated mice. There was a 64% reduction in the mean tumor weight on day 21 in rIL-2–treated mice (1.5 g) and a 78% reduction in tumor weight in r–interferon gamma–treated mice (1.2 g), compared with control mice (3.9 g).

Effect of In Vivo Depletion With Anti–Asialo GM-1

The strain A/J mice (n = 6 per group) were injected IV with anti–asialo GM-1, anti–Lyt-2, or normal rabbit serum one day before commencing on a three-day course of treatment with rIL-2, r–interferon gamma, or control PBS

Fig 2.—Augmentation of cytotoxicity to C1300-neuroblastoma (NRB) in treated mice. Strain A/J mice (n = 6 per group) were injected intraperitoneally with either recombinant interleukin 2 (rIL-2) (10^5 U three times per day) recombinant interferon gamma (rIFN-γ) (10^5 U daily), or phosphate-buffered saline (PBS) in volume of 0.4 mL for three days. On day 4, lysis of C1300-NRB was measured in a four-hour chromium 51–release assay. Similar observations were made using YAC-1 as targets. No killing of P815 was observed.

in doses utilized above. Cytotoxicity of fresh spleen cells was determined on day 4 against YAC-1, C1300-NRB, and P815 as before. The results are shown in Table 3. Pretreatment with anti–asialo GM-1 completely abrogated the effect of r–interferon gamma on NK activity. Surprisingly, however, anti–asialo GM-1 pretreatment did not abrogate the marked cytotoxic activity of spleen cells of rIL-2–treated mice.

In a subsequent experiment, the strain A/J mice were pretreated with specific monoclonal antibody one day before inoculation with C1300 and were randomized to

Fig 3.—Tumor incidence at day 21 decreased from 100% in phosphate-buffered saline (PBS)–treated animals to 50% in animals treated with recombinant interferon gamma (IFN-γ) IL-2 indicates interleukin 2.

Table 3.—Cytotoxic Results With mAb, YAC-1, and C1300-NRB*

Treatment	mAb	YAC-1 100:1	YAC-1 50:1	C1300-NRB 100:1	C1300-NRB 50:1
PBS	NRS	7.5	2.3	4.5	1.5
	Anti–asialo GM-1	1.5	0	0	0
	Anti–Lyt-2	7.9	4.5	5.5	2.5

Interferon gamma	NRS	27.2	17	14	8
	Anti–asialo GM-1	2.2	0.5	0	0
	Anti–Lyt-2	26.3	17.5	12	7.5
In vitro activated NK cells† (positive control)	. . .	69	59	57	30

*Mice (five to eight per group) were pretreated with anti–asialo GM-1, anti–Lyt-2, or normal rabbit serum (NRS) and, 24 hours later, were commenced on a regimen of recombinant interleukin 2 (IL-2) (10^5 U tds), recombinant interferon gamma (10^5 U daily), or phosphate-buffered saline (PBS). Treatment was continued for three days, and on day 4, cytotoxicity to YAC-1, C1300–neuroblastoma (NRB), and P815 was determined. Data are expressed as percent lysis at 100:1 and 50:1 effector–target cell ratios. No killing of P815 was observed. mAb indicates monoclonal antibody.

†In vitro activated natural killer (NK) cells (positive control) were generated by incubating spleen cells in complete medium containing 200 U/mL of recombinant IL-2 for 48 hours.

Table 4.—Tumor Incidence and Weight Results on Day 21 in Strain A/J Mice*

Treatment	mAb	n	Tumor Incidence, %	Tumor Weight, g†
PBS	NRS	8	100	3.9 ± 0.5
	Anti–asialo GM-1	6	100	4.8 ± 1.3
	Anti–Lyt-2	5	100	4.7 ± 2.2
Recombinant IL-2	NRS	8	80	1.5 ± 0.8
	Anti–asialo GM-1	14	100	4.5 ± 1.8
	Anti–Lyt-2	8	100	5.0 ± 1.3
Interferon gamma	NRS	10	50	1.2 ± 1.1
	Anti–asialo GM-1	6	100	5.2 ± 3.7
	Anti–Lyt-2	7	58	6.8 ± 2.7

*Strain A/J mice were injected intravenously with anti–asialo GM-1, anti–Lyt-2, or normal rabbit serum (NRS) one day before subcutaneous inoculation with C1300–neuroblastoma (day 0). Mice were treated with recombinant interleukin 2 (IL-2) (10^5 U three times per day), recombinant interferon gamma (10^5 U daily), or phosphate-buffered saline (PBS) from days 1 through 3.

†Mean ± SD tumor weight.

regimens with rIL-2 or r–interferon gamma. Table 4 indicates the results in terms of tumor incidence and tumor weight on day 21. Either anti–asialo GM-1 or anti–Lyt-2 pretreatment completely abrogated the antitumor effect of rIL-2 and r–interferon gamma.

COMMENT

The challenge in improving the responsiveness of tumors to immunotherapeutic modalities of treatment involves (1) an understanding of the cellular effector mechanisms involved in vivo during the regression of tumors that respond and (2) an understanding of the interaction of tumor components (MHC-regulated or otherwise) with effector cells, such as CTL and NK, and the potential for modulation of this interaction. For human NRB, Main et al[8] demonstrated that human NRB cell lines lacked class 1 antigen and were not susceptible to killing by CTLs but were highly sensitive to NK cell killing. This is consistent with evidence that NK cell killing varies inversely with class 1 expression.[26] The clinical implications of their findings is that the aggressiveness of human NRB may relate to a lack of CTL development by the host, or alternatively, it may relate to impaired NK activity. From a therapeutic viewpoint, tumors, such as NRB with low but inducible class 1 MHC levels, may be suitable for therapies that modulate class 1 MHC levels or for therapies that augment NK activity.

This study demonstrated the immunologic relevance of murine C1300-NRB to human NRB. The NK sensitivity was demonstrated using both basal and Poly IC–induced splenic effector cells from strain CBA/J mice. The C1300-NRB, however, is syngeneic to strain A mice, which is a relatively low-responder strain for expression of natural cytotoxic reactivity to YAC-1, with minimal killing observed in short-term ^{51}Cr-release assays. Herberman et al[27] demonstrated that strain A mice are not generally low reactors in natural cytotoxicity, but are only low in their reactivity against some of the antigens recognized by NK cell mechanisms, including YAC-1. In support of this, we have observed no differences in basal anti–asialo GM-1 receptor expression in strain A/J spleen cells, compared with strain CFW spleen cells, which have a higher basal reactivity against YAC-1. Furthermore, activated NK from strain A mice lyse YAC-1 efficiently in short-term assays.

In vivo depletion with anti–asialo GM-1 resulted in rapid tumor growth and significantly increased mortality by day 21 after inoculation, compared with control mice. These effects were relatively more pronounced than depletion of Lyt-2–positive cells, suggesting that NK cells may have a greater regulatory role than CTLs in untreated animals.

The biologic effects of r–interferon gamma were more marked than high-dose rIL-2 in this study, where treatment was instituted at an early period of tumor development. This was not explained by differences in NK activity as the enhancement of NK cytotoxicity by r–interferon gamma was considerably less than that observed with rIL-2. An immunologic explanation for this effect, rather than an explanation based on a potential antiviral and antiproliferative effect, is likely in view of the fact that pretreatment with anti–asialo GM-1 or anti–Lyt-2 abolished the antitumor effect. This indicates that both cells of the NK and CTL phenotype are required for r–interferon gamma to be effective in this model. There are two likely mechanisms to explain the influence of CTLs in this phenomenon: (1) r–interferon gamma is a potent modulator

of class 2 (Ia) on antigen-presenting cells, such as macrophages and dendritic cells, such that the host capacity to present C1300 and to sensitize host lymphocytes may be enhanced[22]; and (2) r–interferon gamma may directly enhance class 1 and class 2 expression on the tumor in vivo, resulting in enhanced generation of CTLs. In this respect, we have demonstrated that r–interferon gamma at a concentration of 500 U/mL induces class 1 expression on C1300-NRB cells in vitro, with the effect being observed at 24 hours and maximal after 72 hours.[28]

The effectiveness of high-dose rIL-2 in this model was also abrogated by selective depletion of anti–asialo GM-1–positive or Lyt-2–positive cells. Pretreatment with anti–asialo GM-1 did not significantly reduce the enhanced cytotoxic activity against YAC-1 or C1300-NRB. This phenomenon may have involved facilitated non-MHC-restricted lysis of these targets by Lyt-2+ T cells, as has been observed in CTL clones stimulated with rIL-2.[29] The influence of in vivo LAK cell generation in this study is unclear, although we observed no significant killing of the LAK-sensitive P815 cell line by spleen cells from treated mice.

Phase I/II studies evaluating r–interferon gamma in advanced human NRB have been initiated, and augmented NK killing and tumor class 1 expression have been observed in a small study.[30] No clinical response has been observed to date. Perhaps the greatest application of r–interferon gamma will be in low-volume disease, such as following cytoreductive surgery or after multimodality treatment and bone marrow transplantation, since experimental evidence suggests that NK mechanisms and MHC modulation are of greater benefit with smaller tumor burdens. Clearly, future experimental and clinical studies will evaluate r–interferon gamma in combination treatment modalities, with cytokines, such as tumor necrosis factor and rIL-2, and in combination with LAK cell or tumor-infiltrating lymphocytes. Based on the evidence from this study, murine C1300-NRB can be a suitable model for evaluation of such immunotherapeutic modalities.

This study was supported in part by the Georgene S. Harmelin Surgical Oncology Research Fund, Philadelphia.

James Markmann, University of Pennsylvania, Philadelphia, provided the murine interferon gamma and the fluorescein isothiocyanate goat anti–rabbit IgG (ab′)2 used in this study.

Discussion

Q Dr Reynolds, I know you mentioned in the beginning that NRB may be an immunogenic tumor; however, this model is a sub-Q model, and what effect do you think the blood-brain barrier would have on the immune response? How do you think that you could translate a model like this from a mouse system to a human condition?

A This NRB was originally a metastatic tumor, but by years of serial and in vivo transplantation and keeping it in vitro, it lost a capacity to metastasize. In terms of the blood-brain barrier, I am really unsure as to how we could influence that. The only suggestion is, and this is based on work done with human NRB cell lines at The Children's Hospital of Philadelphia, that interferon very potently induces class 1 induction of the human NRB, and specific cytotoxic responses can develop to the tumor in the class 1–induced state. They feel, though they have not proved it experimentally, nor have we, that this may be an important modality for future treatment. Local-sensitized CTLs may exert an antitumor effect on class 1–upregulated NRBs.

Q After the anti–asialo GM-1 therapy, did the NK cell count decrease?

A Yes, it did. It decreased from a mean of about 15% in the untreated state to a mean of about 4% positivity in the treated animals after three days.

Q Now that you have established with this sub-Q model that you can boost the immune response, increase NK activity, and essentially show a difference, where are you going to take this? Is this model something you are going to continue with; what is your next experiment?

A I think the most exciting feature of working with neurotumors, in the experimental system, is that they do not express class 1 antigens. So early treatment with interferon and tumor necrosis factor, which induces class 1 induction on the tumors, followed later on by treatment with potent adaptive immunotherapy, such as LAK cells or tumor-infiltrating lymphocytes, may, I feel, give the best results.

Pseudocysts in Chronic Pancreatitis

Surgical Results in 102 Consecutive Patients

Tuula Kiviluoto, MD; Leena Kivisaari, MD; Eero Kivilaakso, MD; Matti Lempinen, MD

• Preoperative symptoms, diagnoses, and postoperative outcomes in 102 consecutive patients with pancreatic pseudocysts were analyzed. Upper epigastric pain, loss of weight, obstructive jaundice, and sudden arterial bleeding from the pseudocyst were the most common preoperative symptoms. Ultrasonography, computed tomography, and endoscopic retrograde cholangiopancreatography were the most useful diagnostic tools in the evaluation of the presence, size, location, and possible pancreatic ductal communications of the pseudocyst. In a single thick-walled pseudocyst, the best long-term results were achieved by internal drainage. Pancreatic resection is justified if the patient already has diabetes or multiple pseudocysts or if the pseudocyst is not amenable to internal drainage. The most fatal preoperative complication was a sudden arterial bleeding from a pseudocyst. In treating this complication, hemostasis with transcystic arterial ligation and external drainage of the pseudocyst gave the best results.
(*Arch Surg* 1989;124:240-243)

Several unsettled questions still exist with regard to the optimal timing and different methods of surgery for pancreatic pseudocysts. Nowadays, ultrasonography (US), computed tomography (CT), and endoscopic retrograde cholangiopancreatography (ERCP) can possibly make the exact preoperative determination of the wall thickness, diameter, number, and size of pseudocysts. Thus, there are improved premises for exact planning of the treatment, as well as for comparing the surgical results. In 1981, Crass and Way[1] emphasized the importance of distinguishing between acute pseudocysts following an attack of acute pancreatitis and pseudocysts associated with chronic pancreatitis. Obviously, the pathophysiology, natural history, and treatment are different in these two conditions.

With regard to the operative treatment of uncomplicated pseudocysts, one should choose between several different operative techniques, including external and internal drainage of the pseudocyst, as well as pancreatic resections.

This study reviews 102 consecutive patients who underwent operations for pancreatic pseudocysts. All patients had chronic pancreatitis. Preoperative symptoms, diagnoses, timing of the operation, and postoperative outcomes after different operations were analyzed.

Accepted for publication April 12, 1988.

PATIENTS AND METHODS

Between 1971 and 1984, 102 patients underwent operations for pancreatic pseudocysts caused by chronic pancreatitis at the Second Department of Surgery, Helsinki University Central Hospital. The mean age of the patients was 39 years (age range, 20 through 71 years). There were 81 men and 21 women. Alcohol was the principal causal factor for chronic pancreatitis in 87 (85%) of the patients. The first pancreatic attack was diagnosed, on an average, four years (range, one to 12 years) before the operation for a pseudocyst. Cholelithiasis was diagnosed in four patients, but none of them had concrements in the common bile duct. In four patients, the pseudocyst was secondary to blunt abdominal trauma. Hyperparathyreosis was detected in two patients, and in five patients, the origin of chronic pancreatitis remained unknown.

The preoperative symptoms are listed in Table 1. More than half (68%) of the patients had upper epigastric abdominal pains that often radiated to the back. A palpable intra-abdominal mass and loss of weight (>5 kg) were other common signs (32% and 27%, respectively). Permanent or intermittent obstructive jaundice (18%) was a sign that suggested compression of the common bile duct by a pancreatic mass. Vomiting (8%) was often evoked by compression of the pyloric outlet or duodenum. Acute bleeding originating from an arterial pseudoaneurysm, secondary to a pseudocyst, occurred in 18 patients (17%). Left pleural effusion, caused by a spontaneous pancreatic fistula, was detected in three patients. Fifteen patients had previously undergone some kind of abdominal operation as follows:

Type of Operation	No. of Patients
Cholecystectomy	4
External drainage of pseudocyst	5
Pancreatic caudal resection	4
Longitudinal wirsungo-jejunostomy	1
Antrectomy and vagotomy	1
Total	**15**

Preoperative Findings

Considerable hemorrhagic anemia with a hematocrit less than 0.34 was present in 24 patients, and in 18 patients (18%), the anemia was attributable to sudden blood loss into the gastrointestinal tract, peritoneal cavity, or retroperitoneal space. Leukocytosis (>10^9/L) was present in ten patients (10%) during the first few days of admission. Usually, the leukocyte count fell to normal

Table 1.—Preoperative Symptoms and Findings in 102 Patients Operated on for Chronic Pseudocysts

Symptom/Finding	External Drainage (n=39)	Internal Drainage (n=22)	Excision/Pancreatic Resection (n=41)	Total

before the surgical therapy. The urine serum amylase values were elevated during the hospital stay in 36 patients (35%) and often showed marked fluctuations. Evidence of extrahepatic biliary tract obstruction with elevation of the serum alkaline phosphatase and/or serum bilirubin levels was noted in 19 patients (19%). In three patients with left pleural effusion, due to a pancreatopleural fistula, the amylase level in the pleural fluid was above 10 000 U/L (Table 1).

In 73 patients (72%), the preoperative diagnosis was confirmed by US, ERCP, and/or CT. In 35 patients, the pseudocyst was localized in the head or uncinate process, in 31, in the body, and in 36, in the tail of the pancreas.

Operations

External Drainage.—Thirty-nine patients (38%) underwent an external drainage of the pseudocyst. This operation was usually chosen in the case of a relatively thin-walled pseudocyst with potentially infected cystic fluid. However, 11 of these patients were operated on by transcystic ligatures for a sudden hemorrhage, originating from a pseudoaneurysm that was generated by an arterial erosion by the pseudocyst.

Internal Drainage.—Single pseudocysts with a thick wall were candidates for internal drainage. In 18 patients (18%), a cystojejunostomy using Roux-en-Y reconstruction with a 35- to 40-cm jejunal blind loop was performed. In one patient, the cystic wall was adherent to the gastric wall, and a cystogastrostomy was performed. In addition, in two patients (2%), multiple intrapancreatic pseudocysts were in connection with the dilated main pancreatic duct, and a lateral wirsungojejunostomy was performed.

Pancreatic Resection.—Pseudocysts, especially multiple ones, destroying pancreatic parenchyma without a dilated main pancreatic duct, were usually treated with resection. Resection of the pseudocyst, only without removal of pancreatic parenchyma, was possible in three patients (3%), whereas in 38 patients (38%), pancreatic resection also was necessary. In four of them, multiple pseudocysts were localized in the head of the pancreas, causing intrapancreatic obstruction of the main biliary tract, and a pancreaticoduodenectomy was performed. In five patients, a distal pseudocyst was removed by caudal pancreatic resection. Because of the dilated pancreatic duct, these patients also underwent distal pancreaticojejunostomy (Table 2).

Follow-up

Seventy-five (74%) of the 102 patients had a checkup examination, on average, 6.5 years after the operation (range, two to 12 years). Thirteen patients had died, and 14 patients could not be traced. In addition to the routine clinical examination and laboratory tests, ERCP was performed in 27 patients, US in 49 patients, and CT in eight patients.

RESULTS

Hospital Mortality

Seven patients died within 30 days after the operation, giving a hospital mortality of 7%. One patient died of cardiac insufficiency after an elective pancreatic resection with distal pancreaticojejunostomy (DuVal). The other six patients died after an emergency operation due to a massive hemorrhage from the pancreatic pseudocyst. Two

Table 3.—Surgical Procedures and Clinical Outcome of 18 Patients Operated on for Pancreatic Pseudocyst and Hemorrhage

	No. (%)		
	Transcystic Arterial Ligation (n=11)	Distal Pancreatic Resection (n=5)	Whipple's Procedure or Total Pancreatectomy (n=2)
Reoperation	4 (36)	1 (20)	0
Hospital mortality	2 (18)	3 (60)	1 (50)
Late mortality	2 (18)	0	0
Good postoperative outcome	4 (36)	1 (20)	1 (50)

of these patients had primarily undergone transcystic arterial ligation and external drainage of the pseudocyst. After the operation, one patient had massive bleeding from the gastroduodenal artery during the primary operation, and the other patient died of a rebleeding from the superior pancreatoduodenal artery 22 days after the operation. Four patients died after a left-sided pancreatic resection or total pancreatectomy. The reasons for death were postoperative bacterial sepsis with diffuse intra-abdominal and/or gastrointestinal bleeding in two of these patients, and general sepsis and wound dehiscence in the remaining two patients.

Postoperative Complications

External Drainage.—Six patients underwent reoperations for recurrent pseudocysts after primary external drainage, and pancreatic resection was performed. Three patients developed a persistent pancreatocutaneous fistula after an operative external drainage of a pseudocyst; the treatment in these patients was a sparing distal pancreatic resection. Similarly, two patients were operated on for massive pseudoaneurysmal hemorrhage by hemostatic transcystic ligature and external drainage; they developed a new bleeding episode, and a pancreatic resection was performed.

Internal Drainage.—There was no hospital mortality in this group. Postoperatively, three patients developed pneumonia. Later on, four patients underwent pancreatic resection for abdominal pains and recurrent attacks of pancreatitis. In addition, one patient had sudden bleeding from a pseudoaneurysm in the wall of the pancreaticoduodenal artery. This patient underwent a total pancreatectomy, and died a few days later for a disseminated intravascular coagulation–like diffuse bleeding and sepsis.

Pancreatic Resection.—Recurrent pseudocysts developed in four (13%) of the 32 patients who were primarily treated by a distal pancreatic resection. Three of these patients were treated by an additional pancreatic resection, and internal drainage of the pseudocyst by a jejunal Roux-en-Y procedure was performed in the remaining patient. In addition, four other patients needed an extensive pancreatic resection due to progression of chronic pancreatitis. One patient had signs of biliary tract obstruction with elevated serum alkaline phosphatase and bilirubin levels, but without subjective symptoms. The patient had these symptoms one year after near-total pancreatectomy (leaving a rim of pancreas along the duodenal loop).

In three asymptomatic patients, a silent pseudocyst was revealed by using US, CT, and/or ERCP in the checkup examination. In addition, ERCP and CT showed a noticeable progression of chronic pancreatitis in 15 of the patients.

Fourteen (19%) of the 75 reexamined patients were unable to work because of symptoms attributable to chronic pancreatitis.

COMMENT

Several factors should be considered in the choice of a suitable surgical method for the treatment of pancreatic pseudocysts in chronic pancreatitis. Important factors include the general condition of the patient, pancreatic endocrine and exocrine functional capacity, as well as the site, number, and possible complications of the pseudocysts. Mechanical obstruction of the biliary tract and gastric outlet is clinically important. The differential diagnosis between pseudocysts and other inflammatory masses and neoplasms is also necessary. Ultrasonography combined with fine-needle biopsies, CT, and ERCP are the most important diagnostic tools in the evaluation of these patients.

Most authors agree that resection of the pancreas with a pseudocyst is, in certain cases, indicated.[2-7] Without dilatation of the main pancreatic duct, multiple pseudocysts that constitute the head of the pancreas are not appropriate for the internal drainage procedure, and resection of the proximal portion of the pancreas is often the only possibility. In such situations, our method of choice is usually pancreaticoduodenectomy (Whipple's procedure) or duodenum-saving near-to-total pancreatectomy. Resection is also often indicated, when the patient already has severe pancreatic endocrine insufficiency. However, diabetes and steatorrhea, often combined with continual alcohol consumption, impaired the late results in these patients.

Internal drainage of the pseudocyst with a Roux-en-Y cystojejunostomy proved to yield the best short- and long-term results. In this respect, our results are in accordance with those found by several other authors.[5,8,9] Also, when the pseudocysts are in connection with the dilated main pancreatic duct, lateral wirsungojejunostomy with Roux-en-Y reconstruction often seems to yield satisfying results.[8]

In our series, only one patient had undergone cystogastrostomy, and he needed a new operation because of recurrence of the pseudocyst. However, this procedure is often advocated in cases when a mature pseudocyst extends out from the lesser sac and is intimately adherent to the posterior wall of the stomach; this procedure seems to yield satisfactory results in these cases.[5-8,10]

The complication rate was clearly highest (24%) after external drainage of the pseudocysts. Also, in the literature, the complication rate ranges from 25% to 50%.[11] Furthermore, the recurrence rate after this procedure is high, ranging from 20% and 30%.[12] These results strongly suggest that this procedure is rarely warranted in elective surgery.

The most serious complication of a pseudocyst was acute bleeding due to erosion and aneurysmal degeneration of the splanchnic arteries on the wall of the pseudocyst (Table 3). These patients had a very high postoperative mortality (33%). In our series, seven patients of the total 18 patients

with pseudoaneurysmal bleeding underwent pancreatic resection as the primary intervention.[13] Four of these patients died during the first month after the operation. The general condition of these patients was often poor due to massive bleeding, and resectional surgery as an emergency intervention therefore carries a very high complication risk. Our results favor a more "conservative" surgical approach, such as hemostasis with transcystic ligatures with external drainage, for the treatment of this complication, yielding clearly a better outcome. However, in selected cases, good results seem to be achieved also by angiographic arterial embolization,[14,15] but we do not have any personal experience with this method in the management of this complication. Obviously, transcystic ligature and other pancreatic parenchyma–sparing procedures are not always successful, and more extensive surgical interventions, such as pancreatic resection, become mandatory.

The diagnosis of a pseudocyst may be difficult, particularly in situations where pleural effusion is the first sign of pancreatic disease. One of our patients had undergone a left pleural decortication before the correct diagnosis. A high amylase concentration in the pleural fluid is characteristic of this condition. In our series, three patients had a distal pancreatic pseudocyst and pleural fistula. A sparing distal pancreatic resection and removal of the cyst yielded good short- and long-term results.

Unexpectedly, a high frequency of preoperative complications were encountered in the patients with chronic pancreatitis and pseudocysts. Also, improved preoperative diagnostic methods have revealed that the frequency of silent pseudocysts is much higher than was earlier presumed. Prolonged waiting before the operation carries a high morbidity and mortality risk.[2,6,16,17] Thus, early and elective surgery in this disease is recommended.

Editorial Comment

There appears to be less uniformity to pancreatitis and its complications from country to country than exists for many other surgical diseases. This large series of pancreatic pseudocysts from Finland, whose citizens appear to be no less vigorous in their alcoholic consumption than our own, reflects some clear differences. Fewer had pain, and none had pancreatic abdominal ascites, which is surprising. In contrast, the incidence of jaundice (18%) is unusually high. No less than 17% had the dreaded complication of acute bleeding from a pseudoaneurysm in the pseudocyst wall, and these had a 33% mortality rate. The authors note that arterial embolization was not available for these patients, but it may also be significant that recurrent bleeding caused death in some patients in whom transcystic ligation of the aneurysm was performed rather than resection. In our experience, resection, whenever feasible, is the more desirable and, ultimately, safer approach.

Considering that all the operations were done for well-established pseudocysts associated with chronic pancreatitis, the frequency of external drainage (38%) is surprisingly high. Paradoxically, the resection rate of 40% was also unusually high when compared with most series, but the authors may have been ahead of their time in that there is an increasing use of resection in many institutions today. The ratio of 21:1 for cystojejunostomy/cystgastrostomy is unusual although essentially unimportant, and a concomitant lateral pancreaticojejunostomy (modified Puestow) for pain was infrequently added.

Finally, no mention is made of percutaneous or transgastric drainage of pseudocysts. Although not introduced until recent years, consideration of the role of these approaches, desirably based on a preliminary endoscopic retrograde cholangiopancreatography road map, is increasing.

Single-Dose Antibiotic Prophylaxis in Contaminated Abdominal Surgery

John C. Hall, FRACS; J. McK. Watts, FRACS; Lexi Press, RN; P. O'Brien, FRACS; J. Turnidge, FRACP; P. McDonald, FRACP

• Although perioperative antibiotic cover reduces the incidence of septic complications associated with abdominal surgery, the optimum duration of antibiotic exposure is open to question. This clinical trial compared the efficacy of a single dose of moxalactam (1 g intravenously) with an extended course of moxalactam (1 g intravenously for eight doses) in 1027 patients undergoing contaminated abdominal surgery. The wound infection rate was 5.4% (28/519) for the single-dose schedule and 6.1% (31/508) for the extended-cover regimen (the respective 95% confidence intervals being 3.6% to 7.7% and 4.2% to 8.5%). Over 80% of all patients undergoing abdominal surgery during the period of study were entered into the trial. There was no significant difference in the incidence of other complications between the two groups under study. It is concluded that a single dose of moxalactam is as effective as a 48-hour course when attempting to prevent infection after contaminated abdominal surgery.

(*Arch Surg* 1989;124:244-247)

It has been suggested that a single dose of an appropriate antibiotic will provide adequate prophylaxis against infection in patients undergoing contaminated abdominal surgery. Single-dose prophylaxis is attractive because it minimizes the development of bacterial resistance, reduces the risk of morbidity associated with the use of antibiotics, and is cheaper than more prolonged regimens.

However, the evidence in support of this concept contains major deficiencies. Most of the studies addressing this question have either compared a single-dose regimen with a placebo or have compared a single dose of one agent with the prolonged administration of other agents.[1] Only a small number of studies[2-4] have used the same antibiotic to compare a single-dose regimen with an extended course (Table 1). Furthermore, the methodological standards of such studies have recently come under close scrutiny.[5,6] In particular, there has been discussion about the dangers of drawing conclusions from studies that have evaluated relatively small numbers of patients (studies that contain a high probability of a type II error). The small sample sizes used in the studies detailed in Table 1 detract from the reliability of the observed results. Another consideration is the evaluation of an adequate spectrum of patients. At the present time, there is a lack of information concerning the relative value of prophylactic antibiotics across a range of contaminated abdominal operations. Most published studies have concentrated on either biliary or colorectal surgery. Far less information is available concerning gastric and small-bowel surgery.

This clinical trial evaluates the efficacy of moxalactam, a semisynthetic, broad-spectrum, β-lactam antibiotic, given as a single dose or as a 48-hour regimen for a range of potentially contaminated abdominal operations. All patients undergoing abdominal surgery during the period of study were considered for entry into this trial, and the number of patients required to substantiate a claim of "no significant difference" has been predetermined using strict statistical criteria.

METHODS

Consecutive patients over 14 years of age undergoing potentially contaminated abdominal surgery at Flinders Medical Centre, Bedford Park, Australia, or the Repatriation General Hospital, Daw Park, Australia, were considered for entry into the study. It was prospectively decided that an absolute difference of 5% in wound infection rates between the groups (ie, 5% vs 10%) would be of clinical significance. A sample size that could reliably detect or reject such a difference using a two-tailed test with a confidence of 95% ($P = .05$) and a power of 80% was estimated to be 1022.[7]

Patients being considered for entry into the trial received 1 g of moxalactam in 10 mL of water intravenously at the time of induction of anesthesia. Because of reports of coagulopathy associated with the administration of moxalactam,[8,9] patients were given 10 mg of vitamin K intramuscularly prior to operation. Informed consent was obtained from all of the patients investigated in this study, and the protocol was approved by the human ethics committees of the participating hospitals.

The following operative procedures were standardized for all patients within the study. Povidone iodine was used to prepare the skin prior to surgery. Nylon suture was used for the closure of the aponeurotic layer of all vertical incisions. Oblique or transverse incisions were closed using an absorbable synthetic suture. Intra-abdominal drain tubes were passed not through the wound but through a separate stab incision. Wound drains, subcutaneous fat sutures, or tension sutures were not used. The maximum depth of subcutaneous fat in the wound was measured in millimeters using a steel ruler. The skin was closed using stainless-steel staples. No local antibiotic or antiseptic preparation was used in the wound. All patients undergoing elective colorectal surgery had a two-day mechanical bowel preparation (no oral antibiotics were administered).

Patients were entered into the study at the completion of their operation using a stratified randomization technique. Envelopes were grouped according to stratification and placed in a box within

the operating suite of each hospital. These envelopes were sequentially numbered, opaque, and sealed. They contained the drug regimen to be used (previously determined on the toss of a coin) and a perioperative data sheet. The clinical details of patients who were not entered into the study by completion of the randomization procedure and were thereby excluded from study were documented.

The stratification groups were as follows: appendectomy; cholecystectomy; bile duct surgery (including exploration of the common bile duct); elective colorectal surgery; emergency colorectal surgery; gastroduodenal surgery (excluding closed procedures, such as highly selective vagotomy, gastroplasty, and fundoplication); and small-bowel surgery. In addition, there was a set of envelopes present to document patients who were excluded from study. The reasons for exclusion from the study were as follows:

Reason for Exclusion	No.
Postoperative antibiotics for residual infection	75
Antibiotics within 48 h prior to operation	74
Viscus not opened at operation	46
Failure to give informed consent	15
Failure to give initial dose of moxalactam	14
History of cephalosporin sensitivity or penicillin anaphylaxis	11
Established renal or liver failure	3
Reaction to initial dose of moxalactam	2
Total	**240**

The major reasons for exclusion were the preoperative or postoperative use of other antibiotics. Preoperative antibiotics were used to treat the primary disease (61), for the management of concurrent disease (eight), and as preventative measures in patients with prostheses (five). Antibiotics were administered in the postoperative period if residual infection was present at the completion of surgery. This clinical decision was made by the attending surgeon and resulted in a minimum of five days of antibiotic therapy. The wound infection rate for these patients while they were in the hospital was 13.3% (10/75). The end result was that 81.3% of all patients undergoing abdominal surgery during the period of study entered the trial, ie, 1034 of 1272.

Patients assigned to the single-dose regimen received no further antibiotic. Patients assigned to an extended-course regimen received 1 g of moxalactam intravenously at six-hour intervals for a further seven doses. This provided a total of 8 g of moxalactam administered within 48 hours. The dosages of moxalactam were chosen to exceed the minimum inhibitory concentration of 90% of strains of *Bacteroides fragilis* (10 mg/L) for six and 48 hours, respectively.

Each patient was evaluated daily while in the hospital by a nurse epidemiologist. The state of the wound and evidence of postoperative morbidity were noted and recorded. *Wound infection* was defined as a purulent wound discharge or a serous wound discharge with culture of pathogenic organisms. A wound infection was classified as *major* if it resulted in an extension of the hospital stay or required dressings at home for more than seven days and as *minor* if neither of these features occurred. Peritoneal infection was declared if pus or peritoneal fluid containing pathogenic organisms was found at operation, if there was spontaneous discharge or needle aspiration of pus from the peritoneal cavity, or if there was a collection of pus present at autopsy. All patients were reviewed during the fifth postoperative week for evidence of wound infection and the final pro forma was completed by the nurse epidemiologist at this time.

Confidential monitoring of the trial was performed using a group sequential analysis technique.[10] This allowed for an assessment of the trial results, after each consecutive group of 100 patients had been assessed, with the use of an appropriately modified level of statistical significance ($P = .011$). All comparisons of differences between groups were performed using a two-tailed χ^2 test or Fisher's exact test with declaration of the 95% confidence limits.[11]

RESULTS

Five patients were withdrawn from the study because of an inadequate randomization procedure, and two patients were unavailable for follow-up after discharge from the hospital. The equivalence of the stratification procedure for the remaining 1027 patients who completed the study is demonstrated in Table 2. The proportion of patients undergoing emergency surgery varied between the stratification groups, ie, 16.5% (41/248) for colorectal surgery, 27.0% (27/100) for bile duct surgery, 32.2% (91/283) for cholecystectomy, 53.3% (64/120) for gastroduodenal surgery, 87.9% (27/33) for small-bowel surgery, and 99.2% (244/246) for appendectomy.

Pseudomonas aeruginosa	4	1	3
Yeast	2	1	1

*No culture obtained in 13 infected wounds.
†Includes methicillin-resistant *S aureus* (one strain).

The wound infection rates were 5.4% (28/519) for the single-dose schedule and 6.1% (31/508) for the extended-cover regimen (Table 3). There was a considerable overlap of the corresponding 95% confidence limits (3.6% to 7.7% for the single-dose schedule vs 4.2% to 8.6% for the 48-hour schedule), confirming the similarity of the infection rates in the two groups under study. For the single-dose schedule, 12 of the 28 infections were classified as major, compared with 13 of the 31 infections in the extended-cover regimen. No correlation was found between the duration of surgery and the incidence of wound infections. No deaths were attributable to the choice of moxalactam as the prophylactic agent.

The infection rates of each group were monitored using a group sequential technique and began to stabilize after 500 patients had been studied (Figure). Comparison of infection rates within each of the stratification groups also failed to achieve statistical significance, but the relative number of patients in each of these groups is small.

The time of presentation of the wound infections after operation was at a median of eight days, with a range of three to 28 days. No differences in time of presentation of infection was evident between the two treatment groups under study. The median duration of hospital stay was 11 days (range, three to 37 days) for patients having the single-dose regimen and 12 days (range, three to 48 days) for those patients having the extended-cover regimen. Table 4 lists the incidence of other infective or noninfective complications for the two groups. No significant differences between the two dosage regimens was evident for these various complications. The depth of subcutaneous fat, as measured at the time of surgery, was unrelated to the risk of developing an infected wound (Table 5).

Two patients were withdrawn because of possible allergic reactions to moxalactam. Both patients developed a rash soon after administration of the initial dose, and one of the patients had transient respiratory distress that settled without specific therapy. Postoperative bleeding led to reoperation in five patients and to transfusion alone in two patients. A hematologist was consulted on each occasion; however, moxalactam was not implicated in any of these episodes.

Twenty-one (2%) of the 1027 patients died during the course of the study. This mortality reflects the type of patients who were included in this study. The mortalities were as follows: 0% for cholecystectomy (0/283) and appendectomy (0/246); 1.0% (1/100) after bile duct surgery; 3.4% (7/207) after elective colorectal surgery; and 19.4% (13/67) after an emergency resection of the large or small bowel. Information concerning the patients who died during the postoperative period was included in the results (the study was analyzed on an intention-to-treat basis).

The microbiologic features of the wound infections are shown in Table 6. Multiple organisms were cultured in 26 patients or 58% of wound cultures. Nonenteric organisms, most commonly *Staphylococcus aureus*, were cultured as a single or mixed growth in 36 patients (80%). An analysis of the sensitivity patterns of the bacteria confirmed that prophylaxis did not promote the emergence of strains that were resistant to moxalactam.

COMMENT

This study demonstrates that a single dose of moxalactam is as effective as a two-day course of the same antibiotic when trying to prevent infection after contaminated abdominal surgery. No significant differences were noted within the stratification groups. However, two groups with moderate numbers of patients, the appendectomy and elective colorectal surgery groups, both showed trends, but interestingly, in opposite directions.

When the patients who had colorectal surgery (both elective and emergency) were considered as a group, the patients receiving a single dose of moxalactam had a wound infection rate of 10.1% (12/119), compared with 7.9% (10/126) for the 48-hour schedule. While it does not appear that patients were disadvantaged by the use of a single-dose regimen, the overall wound infection rate was still considerable. The same comment can be made for the wound infection rate after gastroduodenal (8.4%) and small-bowel surgery (9.0%).

One factor that might have influenced the wound infection rate relates to the selection of patients. The decision as to whether a patient should be included in this prophylactic study, or receive a full course of antibiotics, was made by the attending surgeon at the completion of each operation. The desire by surgeons to cooperate and enter patients into the trial resulted in the accrual of over 80% of all patients undergoing abdominal surgery during the period of study, but may also have led to the inappropriate inclusion of some patients who had a high risk of developing a septic complication. Against this is the report by Sauvens et al[12] of a wound infection rate of 19.6% (9/46) after ileocolorectal surgery preceded by a similar single prophylactic dose of moxalactam, the report by Hinchey et al[13] of a 7.8% wound infection rate for elective colon surgery after

a three-dose schedule of prophylaxis with moxalactam, and the fact that the rate of wound sepsis observed in this trial compares favorably with that found in other studies.[14]

When designing the protocol for this study, we decided to include all patients undergoing elective cholecystectomy. Many of these patients have a low probability of developing a septic complication; however, it is impossible to identify all of the high-risk patients prior to surgery. In particular, the need for exploration of the common bile duct may only become evident during the course of an operation.

A number of previous studies have demonstrated that the use of perioperative cover alone is at least as good as a "treatment course." Stone and coworkers[15] randomly allocated 220 patients undergoing elective gastric, biliary, or colonic surgery into one group having a three-dose perioperative administration of cefamandole and a further group having this same antibiotic continued beyond the perioperative period for a further five days. No significant differences were found between the groups in the rate of wound infection or other septic complications. In a smaller study Kling et al[16] compared the efficacy of metronidazole and doxycycline in patients having colorectal surgery. Some patients were given a single dose of the agents and some had the antibiotics continued for between two and seven days. Metronidazole was seen to provide more effective prophylaxis than doxycycline. Two of 41 patients having a single dose of metronidazole developed a wound infection and none of the nine patients having prolonged prophylaxis developed wound infection.

Other studies have compared a single-dose schedule with an extended course of the same antibiotic. A study by Strachan and others[2] evaluated cefazolin in 201 patients undergoing routine cholecystectomy. A high rate of wound sepsis occurred in patients used as controls (16.9%), but much lower figures were recorded in patients receiving either a single dose or a five-day course (3.2% and 5.5%, respectively). The investigators concluded that cefazolin "is effective when given as a single dose, which reduces cost, saves nursing time, and is less likely to produce bacterial resistance." Higgins et al[3] reported a small study in which a single dose of co-trimoxazole and metronidazole, given at the onset of colorectal operations, was compared with the use of these same antibiotics for five days. No difference between the treatments was evident (7.0% vs 9.6%, respectively).

A study by Tornqvist et al[4] evaluated the prophylactic effect of doxycycline in elective colorectal surgery. The 196 patients were randomized into four groups. The lowest incidence of wound infection (7%) occurred when 600 mg of doxycycline was administered in the preoperative period, while the highest incidence of wound infection (20%) was associated with the postoperative administration of that antibiotic (the first dose was given in the recovery room).

The results of our study are consistent with the view that it is only necessary to have adequate tissue concentrations of an appropriate antibiotic during the period of contamination. It takes several hours for contaminating bacteria to become localized, and antibiotic drugs administered after this period cannot prevent the development of a septic process.[17] At the present time, the use of cephalosporins with activity against anaerobic bacteria is appropriate when trying to prevent sepsis after contaminated abdominal surgery.[18] Most cephalosporins achieve maximal tissue concentrations within two hours after their intravenous injection and persist at a concentration higher than in the blood for several hours. The administration of a second dose of a prophylactic antibiotic is probably only appropriate when surgery is prolonged. Fry[19] recommended that prophylactic antibiotics should be given twice as often as therapeutic regimens. For example, a second dose of moxalactam would only be necessary if an operation was still in progress three hours after the initial dose was given.

Cephalosporins, such as moxalactam, that contain a methylthiotetrazole side-chain are capable of inhibiting vitamin K utilization by the liver.[8] The hypoprothrombinemia can be prevented or reversed by vitamin K therapy. Although this is more likely to occur in patients with renal failure who are receiving prolonged courses of therapy, it has also been reported after short-term therapy in healthy patients.[9] Prophylactic vitamin K was administered during this study, and there was no clinical evidence of an increased tendency for the patients to bleed. This contrasts with the findings of Morris et al,[20] who found that the administration of vitamin K failed to prevent excessive bleeding in five patients after colorectal surgery. Salem et al[21] refrained from using vitamin K prophylaxis in a careful study of 40 patients and concluded that there was no difference between moxalactam and piperacillin in their ability to produce clinical disturbances of hemostasis.

Although the search for the "best" prophylactic antibiotic for patients submitted to contaminated abdominal surgery will continue, the results of this clinical trial confirm that a single preoperative dose of an appropriate antibiotic provides optimal prophylaxis against infection.

Long-term Survival in Carcinoma of the Biliary Tract

Analysis of Prognostic Factors in 146 Resections

Kiyoaki Ouchi, MD; Seiki Matsuno, MD; Toshio Sato, MD

• In 146 consecutive patients undergoing resection for carcinoma of the biliary tract, various tumor characteristics that affected long-term survival of the patients were studied. Patients with gallbladder carcinoma whose tumors had no serosal infiltration or vessel invasion were grossly papillary, or were papillary or well-differentiated adenocarcinoma histologically survived longer than those without these tumor characteristics. In upper-third lesions, patients whose tumors showed no serosal infiltration or vessel invasion, were grossly papillary, were papillary or well-differentiated adenocarcinoma histologically, or were treated with hepatic lobectomy had a higher chance of long-term survival. Patients with the middle-third lesions, whose tumors were grossly papillary or nodular or whose margins were tumor-free, were apt to survive longer. Long-term survival for patients with lower-third lesions was obtained most often in patients without lymph node metastasis or vessel invasion.

(*Arch Surg* 1989;124:248-252)

Carcinomas of the extrahepatic biliary tract, including the gallbladder, are almost always accompanied by an unfavorable prognosis. In most cases the resectability rate is low because of the direct extension of tumor to adjacent vital organs. Even though the diagnostic methods, surgical techniques, and appropriate chemotherapy or radiotherapy or both have improved, the management of these patients has been extremely difficult. Conversely, there have been reports of long-term survival following resection.[1,2] The published studies have concluded that, whenever possible, aggressive resection is the best approach to these diseases.[3,4]

In an effort to identify various factors that might have prognostic value, the records of patients treated for resection of these carcinomas at the First Department of Surgery, Tohoku University Hospital, Sendai, Japan, were reviewed.

Accepted for publication May 15, 1987.

MATERIALS AND METHODS

The complete clinical records of all patients with histologically proved carcinomas of the biliary tract treated between April 1960 and September 1986 were reviewed retrospectively. Carcinomas of the gallbladder were included, while those of the intrahepatic bile ducts and ampulla of Vater were excluded.

Of 146 patients with carcinoma of the biliary tract who underwent resection, carcinoma of the gallbladder was found in 43 patients and carcinoma of the bile duct was found in 103 patients. The upper third was involved in 36 patients, the middle third was involved in 21 patients, and the lower third was involved in 46 patients.

Of the 43 patients with carcinoma of the gallbladder, 16 were treated with simple cholecystectomy, 25 were treated with cholecystectomy (including wedged resection of the gallbladder bed of the liver and regional lymphadenectomy, namely, extended cholecystectomy), and two were treated with right hepatic lobectomy. Of the 36 patients with carcinoma of the upper bile duct, ten underwent hepatic resection associated with bile duct resection with hepaticojejunostomy and 26 underwent bile duct resection with hepaticojejunostomy. Of the 21 patients with carcinoma of the middle bile duct, six received pancreaticoduodenectomy and 15 received bile duct resection with hepaticojejunostomy. All patients with carcinoma of the lower bile duct were treated with pancreaticoduodenectomy except for one, who underwent total pancreatectomy.

Resection was not indicated when the common or proper hepatic artery or portal trunk or both were involved and when liver metastasis, distant metastasis, or peritoneal seeding was observed.

The patients were divided into two groups. Patients with carcinoma of the gallbladder who survived more than five years and those with carcinoma of the bile duct who survived more than three years constituted group 1 (long-term survivors). The patients with carcinoma of the gallbladder and bile duct who died within five and three years, respectively, constituted group 2 (short-term survivors). Patients who died within one month after surgery and those with carcinoma of the gallbladder and bile duct alive less than five and three years, respectively (ten cases of gallbladder cancer and four of upper, four of middle, and eight of lower bile duct cancer), were excluded from the analysis of prognostic factors. Among the long-term survivors with carcinoma of the bile duct, only three patients with upper-third lesions, three with middle-third lesions, and nine with lower-third lesions survived five or more years after operation. Therefore, the analysis of prognostic factors for cancer of the bile duct was undertaken between three-

Table 1.—Patients Undergoing Resection

	Cancer of Gallbladder	Cancer of Bile Duct		
		Upper Third	Middle Third	Lower Third
No. of patients resected	43	36	21	46
No. of long-term survivors	10	4	5	14
No. of short-term survivors	19	23	9	20

year survivors and the patients who died within three years. Group 1 consisted of ten patients with carcinoma of the gallbladder, four with carcinoma of the upper bile duct, five with carcinoma of the middle bile duct, and 14 with carcinoma of the lower bile duct (Table 1). In group 2 there were 19 patients with carcinoma of the gallbladder, 23 with carcinoma of the upper bile duct, nine with carcinoma of the middle bile duct, and 20 with carcinoma of the lower bile duct.

Retrospective studies were made to search for statistically significant prognostic indicators between both groups for each location of lesion. The indicators studied were as follows: the gross and microscopic features of tumors; depth of invasion; lymph node metastasis; infiltration to the liver, the duodenum, or the pancreas; involvement of major vessels; histologic venous, lymphatic, or perineural invasion (vessel invasion); resected margin; and types of operative procedures. All statistical analyses were done by the χ^2 method. Cumulative survival rates for patients with each type of lesion of the biliary tract system were obtained by the Kaplan-Meier method.

RESULTS

Operations

The resectability rate for gallbladder carcinoma was 30% (43/144), with a mortality of 9% (4/43) (Tables 2 and 3). Lesions in the upper, middle, and lower third of the bile duct were resectable in 31% (36/117), 45% (21/47), and 60% (46/77) of the patients admitted, respectively. Resection was associated with 14% operative mortality in carcinomas of the upper (5/36) and middle bile ducts (3/21) and with 9% (4/46) in carcinoma of the lower bile duct.

When the cumulative postoperative survival rates, including operative mortality, were analyzed according to the location of the lesion, the five-year survival rates were as follows: gallbladder carcinomas, 41%; upper-third lesions of the bile duct, 17%; middle-third lesions, 20%; lower-third lesions, 29% (Fig 1). The exact cause of late death was often difficult to ascertain, but, in the majority of patients in group 2, death was directly related to the biliary tract, ie, progressive or recurrent tumor or liver failure.

Prognostic Factors

Cancer of the Gallbladder.—Eight of ten patients in group 1 were alive with disease-free conditions. All patients in group 1 had tumors superficial to the subserosa; three showed only mucosal, four showed muscular, and three showed subserosal involvements. Conversely, there was spread of tumors beyond the gallbladder serosa in 14 (74%) of 19 patients in group 2 ($P<.01$ compared with group 1, Fig 2). Hepatic infiltration of carcinoma was found in one of the ten patients in group 1 and 11 (58%) of the 19 patients in group 2, and there was a statistically significant difference in the presence of hepatic infiltration between groups 1 and 2 ($P<.05$). The gross pathologic findings revealed that in group 1 seven of ten patients had tumors associated with the papillary form, while in group 2 thirteen (68%) of 19 patients had tumors of the infiltrative or nodular form; this difference was statistically significant ($P<.05$). With respect to the microscopic findings, group 1 consisted of nine papillary and one well-differentiated tubular adenocarcinomas, while eight patients in group 2 (42%) had moderately or poorly differentiated tubular adenocarcinomas. This difference was significant ($P<.05$). Venous, lymphatic, or perineural invasion or a combination thereof was found by histopathologic examination in three (30%) of ten patients in group 1 and in 16 (84%) of 19 patients in group 2. Thus, the presence of vessel invasion differed significantly between groups 1 and 2 ($P<.01$). In group 1, five patients survived five or more years after simple cholecystectomy; three had tumors limited to the gallbladder mucosa and two had tumors limited to the muscular layer. The remaining five patients in group 1 underwent extended cholecystectomy; two had tumors limited to the muscular layer and three had tumors limited to the subserosal layer. Conversely, in group 2, nine died after simple cholecystectomy and ten died after extended cholecystectomy. The former included patients with involvement of the mucosa (one), the muscular layer (three), the subserosal layer (one), and the serosal layer (four). All of the latter ten patients had tumors exposed to the serosa.

Cancer of the Upper Bile Duct.—Three (75%) of four

Upper third	36	5	14
Middle third	21	3	14
Lower third	46	4	9

Fig 1.—Survival curves after resection according to location of lesion within biliary system (Kaplan-Meier method).

Fig 2.—Prognostic factors in carcinoma of gallbladder. Top column, long-term survivors; bottom column, short-term survivors. Depths of cancer invasion in gallbladder carcinoma were classified into mucosal (M), muscular (PM), subserosal (SS), and serosal (S) involvements. Histologic types of tumor were classified into papillary adenocarcinoma (Pap), well-differentiated tubular adenocarcinoma (Tub_1), moderately differentiated tubular adenocarcinoma (Tub_2), and poorly differentiated tubular adenocarcinoma (Por). Comparison with group of long-term survivors gave following results: single asterisk, $P<.05$; double asterisk, $P<.01$.

Fig 4.—Prognostic factors in carcinoma of middle bile duct. Top column, long-term survivors; bottom column, short-term survivors. Asterisk indicates comparison with group of long-term survivors, $P<.05$.

patients in group 1 had no cancer infiltration of the serosa of the bile duct, and two of them had involvement limited only to the fibromuscular layer of the bile duct. In contrast, 18 (78%) of 23 patients in group 2 showed cancer infiltration of the serosa and only five did not (Fig 3). Therefore, in group 2 the presence of serosal infiltration was higher than

Fig 3.—Prognostic factors in carcinoma of upper bile duct. Top column, long-term survivors; bottom column, short-term survivors. Comparison with group of long-term survivors gave following results: single asterisk, $P<.05$; triple asterisk, $P<.001$.

Fig 5.—Prognostic factors in carcinoma of lower bile duct. Top column, long-term survivors; bottom column, short-term survivors. Double asterisk indicates comparison with group of long-term survivors; $P<.01$.

in group 1 ($P<.05$). With respect to the gross findings, the papillary form was seen in three patients. Two of them, belonging to group 1, survived three or more years and died of diseases not related to the carcinoma; their survival periods after operation were 13 and 5.5 years, respectively. The remaining patient with the papillary tumor was still alive without any sign of recurrence 2.7 years after operation. None of the group 2 patients, in contrast, had papillary-type tumors. Group 2 included 19 patients with infiltrative tumors and four with nodular tumors, and this incidence was significantly different from group 1

($P<.001$). Histologic examination revealed there were two papillary adenocarcinomas and two well-differentiated tubular adenocarcinomas in patients in group 1, whereas 15 patients (65%) in group 2 had moderately or poorly differentiated tubular adenocarcinomas. This difference was statistically significant ($P<.05$). Venous, lymphatic, or perineural invasion or a combination thereof was found in two of four patients from group 1 and in 22 (96%) of 23 patients from group 2 ($P<.001$). Margin-free resection could be achieved in all four group 1 patients; two underwent hepatic lobectomy with bile duct resection and two had bile duct resection alone. Although specimens from ten patients in group 2 showed tumor in their margins, the incidence of tumor-free margins was not significantly different from group 1. However, the use of hepatic lobectomy with bile duct resection was significantly more frequent in group 1 than in group 2, in which 22 (96%) of 23 patients underwent bile duct resection alone ($P<.05$).

Cancer of the Middle Bile Duct.—The gross findings indicated that group 1 consisted of one papillary and three nodular carcinomas (Fig 4). In contrast, seven (78%) of nine tumors in group 2 patients were of the infiltrative type. This incidence was significantly higher in group 2 ($P<.05$). The histologic findings revealed that in all cases, carcinoma of the middle bile duct was either papillary or well-differentiated tubular adenocarcinoma, and no difference in the type of histologic shape could be found between groups 1 and 2. Venous, lymphatic, or perineural invasion or a combination thereof was frequently recognized in both groups: four of five patients in group 1 and seven of nine patients in group 2. A tumor-free margin was achieved in four patients (80%) in group 1, which was a significantly better result than in group 2, in which only two patients (22%) had tumor-free margins ($P<.05$). Four of five patients in group 1 and all patients in group 2 underwent bile duct resection alone. One among the group 1 patients underwent pancreaticoduodenectomy.

Cancer of the Lower Bile Duct.—In cases of lower bile duct cancer, there was a higher incidence of pancreatic, duodenal, and major vessel invasion in 20 patients who died within three years after operation (group 2) than in 14 patients who survived three or more years (group 1), but the difference was not significant. Lymph node metastasis was found in 14 (70%) of 20 patients in group 2 but was found in only two (14%) of 14 patients in group 1 ($P<.01$, Fig 5). Venous, lymphatic, or perineural invasion was significantly less frequent in group 1 than in group 2 (36% [5/14] vs 85% [17/20], respectively; $P<.01$). No significant difference could be demonstrated for various forms of gross and histologic characteristics of tumors between groups 1 and 2.

COMMENT

Cancers of the gallbladder were associated with a poor resectability rate due to extensive local extension to the adjacent vital organs, which precludes curative resection. Many of the cases were far advanced and extensive when diagnosed because the disease does not cause specific symptoms in its early stage. The disease that is often indicated for curative resection is rarely diagnosed preoperatively. Correct preoperative diagnosis of gallbladder carcinoma was made in 15 of 43 patients who underwent resection and in only two who survived five or more years after operation. The conditions of the remaining eight long-term survivors were diagnosed intraoperatively or after the histologic examination of the resected specimens. Bergdahl[5] found that the majority of patients who lived longer than five years were usually those whose carcinoma was diagnosed during microscopic examination of gallbladders removed for presumed benign disease. Our experience suggests that only when carcinoma is localized inside the gallbladder is there a reasonable chance of long-term survival. Among the ten long-term survivors, macroscopically seven had papillary tumors and, histologically, all except one had papillary adenocarcinoma. No patient with moderately or poorly differentiated carcinoma survived longer than five years. All the tumors limited to the mucosa and six of seven tumors limited to the muscularis layer were of the papillary form. In contrast, 11 of 17 tumors spread beyond the serosa were of the infiltrative type. Papillary adenocarcinoma was found in five of seven tumors with mucosal involvement and in six of seven with muscular involvement. Conversely, of 17 tumors spread beyond the gallbladder serosa, seven had moderately or poorly differentiated tubular adenocarcinoma, which was not found in tumors superficial to the subserosa. Appleman et al[6] reported that in 21 patients who lived five or more years, the gross appearance of tumors was papillary in 12, and ten were histologically well-differentiated carcinoma. It can be said that the prognosis of gallbladder carcinoma is highly influenced not only by the depth of invasion but also by the biologic nature of the tumor, ie, gross and histologic characteristics of tumor. Tumors characterized as infiltrative are frequently associated with venous, lymphatic, or perineural invasion. Eighty-four percent of the patients who died less than five years after operation had venous, lymphatic, or perineural invasion. One patient with a mucosa-limited, well-differentiated, tubular adenocarcinoma and three patients with muscular tumor died of recurrence within five years after performance of simple cholecystectomy. Fahim et al[7,8] reported that the only place for simple cholecystectomy is for noninfiltrative, grade 1 papillary adenocarcinoma. An adequate operation for carcinomas superficial to the gallbladder subserosa should be extended cholecystectomy. Ten patients with tumors spread beyond the serosa died within five years after performance of extended cholecystectomy. Thus, for advanced disease that involves the gallbladder serosa, more than extended cholecystectomy should be performed.

The outcome for patients with carcinoma of the upper bile duct is poor because of the low frequency of curative resection owing to the technical difficulties associated with resection and extension of tumor to the liver or to the main vessels. Resectability rates in recent years have ranged from 25% to 47%.[1,3,9,10] The resectability rates in our series were 31% for all admitted patients and 41% for all operated-on patients. Histologically curative resection (tumor-free resection) was obtained in only 16 of 36 patients who underwent resection. In the series of Beazley et al,[9] only four of 16 patients obtained curative resection. As similarly shown in carcinoma of the gallbladder, morphologic features in carcinoma of the upper bile duct are intimately related to the prognosis of the patients. Macroscopically papillary tumors were seen in half of the three-year survivors and papillary or well-differentiated adenocarcinomas were seen in all of the three-year survivors. Two of three papillary carcinomas were limited to the fibromuscular layer of the bile duct and one was limited to the subserosal layer. Kozuka et al[11] reported that of eight patients with papillary carcinoma, seven with carcinoma limited to the fibromuscular layer showed better prognosis than those having carcinoma of other types. They also mentioned that all the noninfiltrating cancers were papillary adenocarcinomas and all the poorly differentiated cancers had spread beyond the fibromuscular layer. No

patients with poorly differentiated carcinoma in our series survived two or more years. Thirteen of 14 cases of moderately or poorly differentiated carcinoma were associated with venous, lymphatic, or perineural invasion. In our series of patients undergoing resection, two long-term survivors received hepatic lobectomy combined with resection of the bile duct, while a majority of short-term survivors received bile duct resection alone. Excluding hospital deaths, five patients who underwent hepatic lobectomy showed a two-year survival rate of 75% and 20 patients who underwent bile duct resection alone showed a two-year rate of 30%. If the tumor is infiltrative and localized to the confluence of the hepatic ducts, a hepatic lobectomy along with bile duct resection and hepaticojejunostomy should be chosen. Bile duct resection is preferentially indicated only when the papillary tumor is localized to the common hepatic duct. The longest survivor alive and well 13 years after bile duct resection had papillary tumor limited to the fibromuscular layer.

In cancer of the middle bile duct, both gross findings of tumor and resection margins influenced the prognosis of the patients. Most long-term survivors had papillary or nodular tumors, while most short-term survivors had infiltrative tumors. There are considerable difficulties associated with macroscopic evaluation of the resected margins. In our four patients undergoing resections of the bile duct along with Roux-en-Y hepaticojejunostomy, duodenal margins that seemed to be tumor-free during surgery proved to show tumor invasion on histologic examination. As perineural invasion was highly associated with cancer of the middle bile duct, exposed connective tissues around the major vessels in the hepatoduodenal ligament were apt to show cancer invasion. To eliminate cancerous duodenal margins and to dissect pericholedochal and pancreaticoduodenal lymph nodes completely, pancreaticoduodenectomy is highly recommended except for patients with localized and papillary or nodular tumors.

The lesions of the lower third were associated with the best results of resection among lesions of the bile duct, mostly because of the highest resectability rate. Gibby et al[4] failed to demonstrate an increased survival rate with pancreaticoduodenectomy in their nine patients with cancer of the lower bile duct, while Tompkins et al[1] reported the most significant improvement in survival rate with pancreaticoduodenectomy. It is clear that resection carries the best hope of cure. Fourteen patients who had resections survived three or more years, and the longest survivor in our series was alive 12 years after surgery. The results of the present study revealed that prognosis of the patients undergoing resection of carcinoma of the lower bile duct depends on the presence or abscence of lymph node metastasis and venous, lymphatic, or perineural invasion, prognostic factors that are similar to those of cancer of the head of the pancreas.[12] Neither gross nor histologic features of tumors of the lower bile duct were important factors for long-term prognosis, and this evidence was different from other lesions of the biliary tract system. It can be said that in cancer of the lower bile duct, the infiltration to the surrounding tissues is more important than the biologic characteristics of tumor for defining prognosis. The long-term prognosis for patients who had lymph node metastasis and vessel invasions has not been satisfactory even after pancreaticoduodenectomy.

A New Regimen of Interleukin 2 and Lymphokine-Activated Killer Cells: Efficacy Without Significant Toxicity

Timothy J. Eberlein, MD; Deric D. Schoof, PhD; Sung-Eun Jung, MD; David Davidson; Barbara Gramolini, MT(ASCP); Kathleen McGrath, RN; Anthony Massaro; Richard E. Wilson, MD

Adoptive immunotherapy with high-dose interleukin 2 and lymphokine-activated killer (LAK) cells has proved to be successful in the treatment of some patients with metastatic cancer, but not without a significant degree of associated toxic effects. The primary goal of this study was to substantially reduce the toxicity of this complex and expensive treatment, while maintaining or improving efficacy. To this end, 29 patients were treated with LAK cells in conjunction with a low-dose regimen of interleukin 2 and a prolonged period of administration following LAK cell infusion. This protocol resulted in a considerable reduction in toxicity, as compared with that described in previous studies, without compromising the efficacy. This study offers further confirmation that adoptive immunotherapy of metastatic cancer can be clinically beneficial to patients for whom no other effective therapy is presently available (*Arch Intern Med* 1988;148:2571-2576).

Follow-up of Patients With Aspirated Breast Cysts Is Necessary

Hisham Hamed, MD; Andrew Coady, MS; Murid A. Chaudary; Ian S. Fentiman, MD

• A review was conducted of 401 women who presented with breast lumps that proved to be cysts by yielding fluid on aspiration. The aim was to determine the proportion of patients with cancers that masqueraded as cysts and to establish whether short-term follow-up was necessary. After the first visit, six patients had biopsies because of a residual mass or a bloodstained aspirate. Of these patients, two were found to have cancer. After the follow-up visit, 20 further biopsies were carried out for presence of a mass, bloodstained fluid, or recurrent fluid, and two more cancers were diagnosed. Of the four patients with malignancy, only one had an intracystic carcinoma, two had necrotic grade 3 ductal carcinomas, and one had a malignant phyllode tumor. These findings underline the value of a single return visit after cyst aspiration.

(*Arch Surg* 1989;124:253-255)

The appearance of a breast lump may provoke great anxiety in a woman, particularly if the mass appears suddenly. Fortunately, many of these lumps prove to be cysts that disappear after aspiration. Gross cystic disease of the breast was first described by Sir Astley Cooper[1] in 1840, and this condition is the most frequent cause of benign breast lumps. At Guy's Hospital Breast Unit, London, approximately 7% of all new patients are found to have gross breast cysts. Such patients are treated by needle aspiration. Provided that the aspirate is not bloodstained, there is complete resolution of the lump following aspiration, and there are no signs to indicate an underlying malignant neoplasm, they are asked to return to the clinic in six to eight weeks for reexamination. The reason for follow-up is to exclude cyst recurrence and a malignant neoplasm that masquerades as a cyst. This routine review, apart from putting the patient to the inconvenience of another hospital visit, often takes up a considerable amount of the physician's time in a busy clinic. However, with the advent of mammography and its use in symptomatic women aged over 35 years, it is possible that return visits are unnecessary provided that the malignant neoplasm is excluded roentgenographically. Against this, it has been claimed that gross cystic disease of the breast carries a twofold to threefold increase in risk of subsequent carcinoma,[2] and therefore, these patients should be closely monitored. This apparently increased risk was derived from studies in which benign breast disease was considered collectively without detailed histological description. However, recent long-term follow-up studies of patients with histologically characterized benign breast lesions have shown that the risk is only carried by a small proportion of such patients who have atypical epithelial hyperplasia, and this risk is further increased by a positive family history.[3] Attempts have been made to subdivide cysts into flattened and apocrine, based on the biochemical content.[4,5] Dixon et al[6] showed in a retrospective study that 11 of 80 patients with apocrine cysts developed a subsequent malignant neoplasm, as compared with only one of 30 of those patients with flattened cysts. To our knowledge, no prospective study has yet been carried out to assess the significance of cyst type and cancer risk. The aim of this study was to review the experience of a busy breast clinic to determine first the number of cancers that presented as cysts and second whether routine short-term follow-up of those patients with benign cysts was necessary.

PATIENTS AND METHODS

The case records of 401 women with gross cystic disease who attended the Guy's Hospital Breast Unit between 1978 and 1980 were reviewed. The diagnosis of a cyst was made clinically on the basis of a lump that resolved after aspiration. At the time of first presentation, provided that aspiration was successful, bilateral mammography was arranged for those patients aged 35 years or older. The cyst aspirate was not subjected to any routine cytological or biochemical examination. All patients were reviewed six to eight weeks after first attending.

Patients were considered to have had recurrence of a cyst if, at their second visit, there was reaccumulation of fluid at the site of previous aspiration. Those cysts in a different quadrant of the same breast, or in the contralateral breast, were not regarded as recurrences. Repeated aspiration was performed, but a biopsy was carried out if there was a residual palpable mass, if a bloodstained aspirate was obtained, or if there was a recurrence of the cyst at the same site on more than two occasions. Usually, those patients without a recurrence and with normal mammograms were then discharged.

Accepted for publication Dec 3, 1987.

Table 1.—Features at First Presentation With Breast Cyst

Feature	Mean
Age, y	
Mean	45.7
Range	14-72
No. of patients	
Premenopausal	344
Postmenopausal	19
Previous hysterectomy	38
Side of cyst appearance	
R	153
L	215
Bilateral	33
Site of cyst	
Medial	64
Central	95
Lateral	181
Multiple	61

RESULTS

Clinical Features

The clinical features of the patients are shown in Table 1. Three hundred forty-four women (86%) were premenopausal. Thirty-eight women (9.5%) had had a previous hysterectomy, and 19 (4.5%) were postmenopausal (last period more than six months before the visit). It is interesting that of those patients with unilateral cysts, 153 (42%) were right sided, and 215 (58%) were left sided which mirrors the left-sided predilection of breast cancers. Cysts were single in 340 patients (85%) and multiple in 61 patients (15%). The clinical findings after aspiration were as follows:

Finding	No. of Patients
Complete resolution	395
Residual mass and bloodstained aspirate	2
Residual mass	3
Bloodstained aspirate	1

One patient had bloodstained fluid aspirated but without a residual mass. Five patients had a residual mass, and two of these patients also had bloodstained aspirates. A biopsy was performed in all six of these patients with signs that were suggestive of a malignant neoplasm, and a histological diagnosis of carcinoma was made in two patients, both of whom had a residual mass and bloody aspirate. The clinical findings on review six to eight weeks later are shown as follows:

Finding	No. of Patients
No abnormality	315
Mass at site of previous cyst	20
Recurrent cyst	44
New cyst	22

Patients with a mass at the original site of cyst aspiration that did not disappear on the second attempted aspiration are given separately in the above tabulation. Those patients with a mass that was at the site of the original cyst and disappeared after a second aspiration were described as having recurrent cysts. As a result of the finding of recurrence of the cyst on one or more occasions or aspiration of bloodstained fluid or a mass at the site of aspiration, 20 further biopsies were performed. Among these, carcinoma was diagnosed histologically in a further two patients, in both of whom there was a mass at the site of the aspiration. One hundred fifty-five patients had mammography. No biopsies were performed because of mammographic abnormalities alone. A possible explanation was because the majority of these patients were premenopausal with dense breast tissue that could have masked a mass, microcalcification, or trabecular distortion.

Table 2.—Clinical Features of Patients With Breast Cancer Presenting With Cysts

Fibroadenoma	1

Histological Findings

The histological sections from 25 of the 26 patients in whom biopsy specimens were obtained were reviewed, but the slides could not be traced for one patient. (A median of two blocks was taken per case, with a range of one to eight blocks.) Four patients had malignant lesions, and three of these lesions were grossly cystic. One lesion was an intracystic papillary carcinoma, the second lesion was a centrally necrotic grade 3 infiltrating ductal carcinoma, and the third lesion was a malignant phyllode tumor with areas of cystic degeneration. The remaining patient had a grade 3 infiltrating ductal carcinoma that showed extensive necrosis on histological examination, although it was not described as being cystic on gross examination. The clinical features of the patients with biopsy-proved carcinoma are given in Table 2.

The histological features of the 21 benign breast biopsy specimens are shown in Table 3. A large cyst was noted in 13 biopsy specimens, and in five further specimens, three of which had no gross description, an obvious large cyst was identified in the section. Five of the cysts were lined by apocrine epithelium and seven with a flattened epithelium. In many cases, only a small fragment of the epithelium was identified, with the remaining cysts being lined by fibrous tissue without an epithelial lining. In six cases, no lining was demonstrable. There was increased fibrous tissue in the wall of eight of the large cysts, and this was usually accompanied by a chronic inflammatory cell reaction. Two of the three cases in which large cysts were

absent contained microcysts on histological examination. The remaining case showed occasional mildly dilated cuts but no true cyst. Microscopic cysts were present in all but three of the cases in which a macroscopic cyst was identified, and apocrine metaplasia was present in surrounding tissue in all but two of the cases with a large cyst. Ductal epithelial hyperplasia was present in 12 cases, but no examples of atypical hyperplasia of either the ductal or lobular type were seen.

COMMENT

In this study, only 1% of patients presenting with a cystic lump were found eventually to have an underlying malignant neoplasm, and this is consistent with the incidence reported by others.[7-9] Of the entire group of patients, 147 (37%) were followed up for more than one year, 129 (32%) were followed up for more than three years, and 55 (14%) were followed up for more than five years; none of these patients were known to have developed breast cancer. Although a small group of these women were regularly followed up during a long period of time, most return visits were self-referrals as a result of the development of new problems.

A bloody aspirate is not diagnostic of malignant neoplasm as it may be the result of an inadvertent puncture of a blood vessel at the time of aspiration. Similarly, cyst recurrence does not usually imply that there is any underlying carcinoma and is usually due to incomplete aspiration at the first visit. When clinical signs that are thought to be suggestive of a malignant neoplasm were examined in the present study, it was found that the combination of a residual mass and a bloody aspirate were the strongest indicators of underlying cancers. It is of interest that three of the four patients with cystic carcinomas were aged over 60 years.

The main reason for conducting this study was to determine the necessity for short-term follow-up. The results indicate that a review of these patients after six to eight weeks was necessary to detect an underlying malignant neoplasm that was not apparent at the first visit, with one half of the cancers being diagnosed after a biopsy resulting from the second examination.

Provided that the previously mentioned criteria for biopsy are adhered to, a policy of cyst aspiration is safe. However, to reduce the likelihood of overlooking a cystic cancer at the first visit, at least one subsequent reexamination of the breast is recommended after six to eight weeks. Any routine follow-up after this period would appear not to be essential in those patients without recurrence and with normal mammograms. Such a policy would certainly reduce the cost of health care and its burden to the patient. On the second visit to the clinic, the patient can be instructed in self-examination and told to come back if a lump should develop. To minimize patient anxiety, it is helpful to have an open-door policy that affords the patient ready access to the surgeon.

Editorial Comment

This report from a well-recognized breast clinic in England asks if all patients with successfully aspirated, nonsuspicious breast cysts should be *routinely* reexamined in six to eight weeks, and it concludes that they should be. This conclusion is based on the fact that of the 401 patients in the series, one woman aged 72 years had a 3-cm intracystic papillary carcinoma, and another woman aged 69 years had a 7-cm necrotic grade 3 carcinoma that was undiscovered at the first aspiration. The mammographic status of these patients is not known, but their age is highly significant as any distinct cystic (or solid) mass must be viewed with substantial suspicion in all women older than 60 years. It can be conjectured, however, that a combination of self-examination, more accurate initial aspiration, and detailed mammography may well have obviated the subsequent unpleasant surprises experienced by these two patients. Consequently, the data provided do not make an unequivocal case for the hypothesis advanced.

A second visit by the patient three to eight weeks after aspiration is certainly the conventional wisdom and perhaps the safest course to follow as long as the medicolegal atmosphere is as highly charged as it is in the United States. It is a sad fact that lawyers increasingly drive clinical decisions. When the clinical problem is viewed more objectively, however, the concept that routine reexamination is the standard of practice may be vigorously challenged, particularly in a "resource-sensitive" society. Time lost from work, the need often to travel long distances, the high sensitivity of the modern mammogram, the cost of the second visit, and the medical intelligence of many of our patients who are well able to determine the status of their own breasts may justify a telephonic report that confirms the complete regression of the cystic area in question when clear nonsanguineous fluid has been aspirated initially. This is especially true in those patients under the age of 50 years who constitute the significant majority of patients with cysts.

Two or three decades ago, depending on the region of the world, the concept of aspiration of cysts in the breast was an anathema to a great segment of surgeons. Today, the technique and the principles that underpin aspiration are universally accepted. As confidence increased, routine cytological examination of the cyst fluid was advocated as a safety net. The value of this approach has now been disproved. Attitudes change and given the new technology, the increased sophistication of our patients with their desire to share in their own care, and the drive to reduce the cost of medical care, routine reexamination at six weeks of premenopausal patients with successfully aspirated, nonsanguineous cysts and nonsuspicious mammograms is probably unnecessary *as a routine* in this large group of patients.

Treatment of Peritoneal Mesothelioma

To the Editor:—The discussion of management of peritoneal mesothelioma by Plaus[1] is good but incomplete. The behavior of these neoplasms is highly variable in the degree of aggressiveness and the physician risks adding to morbidity by overtreating. The use of a peritoneovenous shunt is not without risk, and with it or without it other approaches may be useful.

In the presence of malignant ascites, copious irrigation of the peritoneal cavity with 5% dextrose in water (DW) at laparotomy is essential. The mucopolysaccharide responsible for the viscosity of malignant ascites (as with pseudomyxoma peritonei) is miscible in 5% DW. Viable tumor cells persist in a third-space haven when this is not done. Pulmonary capillary occlusion and coagulopathies have been reported with peritoneovenous shunts.

The mesothelium is also particularly sensitive to hyperthermia. (We use 5% DW heated to 50°C for a three-minute wash after the wash with 5% DW at body temperature and just before closure.) Finally, whenever intracavitary chemotherapy is administered, each administration must be given diluted to 2000 mL (preferably, 5% DW). This volume is necessary to ensure uniform exposure of the peritoneum to the drug, avoiding streaming and pooling.[2]

Breast Cancer Diagnosis in the Augmented Patient

To the Editor:—Silverstein et al[1] report that in their clinic, breast cancers diagnosed in women with augmentation mammoplasties were more advanced than in nonaugmented patients. They imply that the delay in diagnosis is due to the implant obscuring and compressing the breast, thus reducing the effectiveness of mammography. In light of published evidence that they did not discuss, and in light of potentially serious design flaws in their study, their data do not support their conclusions and should be considered with great skepticism.

Specialty clinics in large urban areas are exceptionally vulnerable to referral bias that can produce overestimations or underestimations of associations. No referral information is provided, and the fact that none of the augmented patients presented until their masses had been palpable for up to two years (mean, 123 days) suggests that the behavior of these patients may be much different from that of the nonaugmented patients.

The ages of the two groups differ substantially, and both the rate of disease progression and screening behavior are likely to be associated with age. While the authors eliminated the nonaugmented patients over age 58 years as an *age adjustment* (an uncustomary usage of the term), they offer no evidence that the age distributions are similar other than comparing means.

We have published a retrospective cohort study[2] of the relationship between breast cancer and augmentation mammoplasty in 3111 patients. Although the authors cite our reference as evidence that implants do not increase cancer risk, they ignore our findings in the relatively early stage of diagnosis when compared with population-based Los Angeles County data. We are now in the process of adding five more years of information and, thus far, have identified 17 breast cancers in this cohort. The stages at detection are as follows: in situ, two; local, eight; regional spread, four; distant spread, two; and unknown, one. The following tabulation illustrates that the breast cancer stage distribution at diagnosis was not different for patients with implants when compared with 5876 women with breast cancer, aged 45 to 54 years and diagnosed between 1972 and 1985:

	All Patients in Los Angeles County, %	Implant Patients in Los Angeles County, %
In situ	7.1	12.5
Local	50.2	50.0
Nonlocal	42.7	37.5

Of the nine cancers detected in patients in the published report (1972-1981), seven were self-discovered as a mass. No detection information is available for the other two. Of the eight cancers diagnosed in patients between 1982 and 1986, three were discovered by routine mammography, and five presented as a mass. Thus, we conclude that breast cancer diagnosis in augmented patients is comparable with the nonaugmented population.

Modern mammography offers the best opportunity for early detection of breast cancer. Film quality in the augmented patient can be comparable with that of the normal breast if one uses the adjustment in technique described by Eklund,[3] supplemented on occasion by some extra tangential views. The pictured mammograms (Figure) were taken by the same tech-

Left, Mammogram taken utilizing conventional technique. Right, Mammogram taken utilizing Eklund's modification (reversed for contrast).

nician on the same patient with the same equipment five minutes apart. The picture on the left utilized conventional technique, and the one on the right (reversed for contrast), Eklund's modification. One should not ignore, of course, the additional detection modalities of self-inspection and regular physical examination by a physician familiar with the implanted breast.

Considering the available evidence to date, we are concerned that this report may foster undue concern among women with breast implants, and fear that it could in fact lead these patients to the unfortunate belief that mammography is of no value. The major cause of delayed detection of cancer in all patients remains ignorance, neglect, denial, and complacency. In an article making several procedural recommendations, we believe a balanced and critical discussion of the evidence should have been presented.

In Reply.—My colleagues and I wish to thank Drs Brody and Deapen for their letter and continued interest in our article.

The typical American woman with breast cancer presents with a palpable lesion with an average diameter of 2.7 cm, with symptoms that have persisted approximately one to three months, and with metastases to axillary nodes 40% of the time. Our group of previously augmented patients with breast cancer and their group both have patients who are quite similar to this average patient with breast cancer. Neither of the groups' patients have early breast cancer by current standards.

Drs Brody and Deapen have 17 previously augmented patients, 38% of whom had positive nodes; our article presented 20 patients, 65% of whom had positive nodes (we currently have 27 patients, 56% of whom had metastases to axillary nodes at the time of presentation). The Los Angeles County registry has 5876 similarly aged, nonaugmented patients, 43% of whom had positive nodes. All of these patients are representative of average breast cancer; therein lies the problem: we should not be satisfied finding average breast cancer.

Fig 1.—Preaugmentation mammogram (craniocaudal view) in 30-year-old woman with average-sized breasts reveals 166 cm² of visualizable breast tissue.

Fig 2.—Postaugmentation mammogram using standard (implant compression) technique reveals 61 cm² of visualizable breast tissue, a 63% reduction. The silicone-gel–filled implant is in subglandular (prepectoral) position.

Fig 3.—Postaugmentation mammogram using Eklund (implant displacement) technique reveals 90 cm² of visualizable breast tissue, an improvement when compared with implant compression technique, but more importantly, a continued reduction of 46% when compared with preaugmentation view.

Early and more curable breast cancers are found by mammography alone. Microcalcifications, asymmetries, architectural distortions, tiny stellate masses, etc, are the only findings, and they are roentgenographic findings. There are no physical findings. There is no palpable lesion. Biopsy must be done using needle, dye, or hooked-wire–directed techniques. Breast cancer diagnosed this way represents the state of the art. Five-year survival rates for this type of patient are in excess of 90% to 95%, compared with 50% to 70% for patients presenting with palpable lesions. Nodal positivity using state-of-the-art screening mammography has been reported to be as low as 4%.[1] Any procedure that interferes with our ability to radiographically visualize breast tissue interferes with our ability to find and diagnose these early nonpalpable lesions. Such a procedure should be challenged.

Hayes and colleagues[2] have published a warning for plastic surgeons and their augmented patients. They

report that 22% to 83% of visualizable breast tissue is obscured by augmentation mammoplasty. Hayes et al state that "this wide variation casts serious doubt on the reliability of routine film-screen mammography in these patients."

Drs Brody and Deapen submit mammograms taken with the conventional (implant compression) technique and Eklund's modification (implant displacement) as evidence that good mammograms can be taken in augmented patients. Unfortunately, they omit the most important film: the preaugmentation mammogram. We are currently completing a study involving more than 50 patients that compares the preaugmentation mammogram with postoperative mammograms done using both the compression and displacement technique. In subglandular (prepectoral) augmented patients, the compression technique obscures an average of 47% (range, 15% to 87%) of visualizable breast tissue. The displacement technique, while better, continues to obscure an average of 31% of visualizable breast tissue (Figs 1 through 3). In addition, as the capsular scar increases, the displacement technique becomes less effective.

When the implant is placed submuscularly and the displacement technique is used, there is no significant loss in visualized square surface area. However, all augmented patients, regardless of the position of the implant, develop some degree of postoperative scarring, which results in various degrees of parenchymal distortion and makes mammographic interpretation more difficult. We caution plastic surgeons not to delude themselves into believing that postaugmentation mammography is as accurate as preaugmentation mammography.

There is nothing wrong with augmentation mammoplasty for properly informed patients. It is, however, the plastic surgeon's duty to inform patients that state-of-the-art mammography, which is the current "gold standard" for early breast cancer diagnosis, will no longer be possible after augmentation. Patients who are at high risk for the development of breast cancer should be discouraged from undergoing augmentation mammoplasty.

We must confront one additional criticism, that is, the mean delay of 123 days in our patients between the first onset of symptoms and diagnosis. We should have reported the median delay, which was 21 days. The elongated average delays occurred because of four patients whose symptoms persisted one to two years. Three of these patients had been reassured by their plastic surgeons that the lump they were feeling was capsular scarring.

Books

Medicine: Preserving the Passion, by Phil R. Manning and Lois DeBakey, New York, Springer-Verlag NY Inc, 1987.

There is some obfuscation associated with the title of this monograph, and the authors use a somewhat compromising approach to data procurement. The title suggests that here is an evangelistic presentation intended to get the juices flowing and rekindle our excitement for our chosen profession. There is also the anticipation that Dr Manning will teach us how to continue learning and Dr DeBakey will focus on how to improve our writing skills.

The book is a well-constructed collection of anecdotal observations obtained by interviews from recognized leaders in medicine. These are supplemented by quotations from notables such as Samuel Johnson ("Curiosity is, in great and generous minds, the first passion and the last") and Seneca ("Men learn while they teach").

There is a collection of "personal essays" produced by 11 accomplished physicians and educators directed at describing the various techniques of continued learning these individuals have developed over the years that have contributed to their success. While some of the methods are general, such as working hard and using time efficiently, others are very specific. As an editor of the *Year Book of Medicine*, for example, Dr Greenberger at the Kansas University School of Medicine, Kansas City, receives 10 000 articles a year to review for possible inclusion in the *Year Book*, providing an obvious continuing education. Accompanying each personal commentary are laudatory phrases and statements concerning the commentators from recognizable peers, indicating the strength of the commentators' credentials.

There is a serious imbalance between information and photographs in this book. The value or purpose of the plethora of photographs of the people being quoted is unclear. Several individuals are quoted in a single brief phrase or sentence, yet there is a full-page photograph. One feels as if one has purchased a photo album.

The book is replete with useful information directed at stimulating and helping physicians improve their self-education patterns. Two chapters deal with the educational characteristics of female physicians and the role of physicians' families. Both chapters are directed at the overall aspects of women as physicians and at the interactions of the physicians with their families and, of course, provide useful information.

The final chapter, which discusses computers in continuing medical education, is excellent and should stimulate all of us to dust off our personal computers and get going.

I hope that Drs Manning and DeBakey will now write about their ideas on continuing to learn and write.

DONALD L. KAMINSKI, MD
St Louis

Abdominal Wound Dehiscence, by Galen V. Poole, Jr, 129 pp, Potts Point, Australia, MacDonald Futura, 1987.

Few complications in general surgery are as distressing for the patient or as embarrassing for the surgeon as an abdominal wound dehiscence. The responsibility for most of these mishaps rests with the surgeon, as dehiscence usually occurs before significant fascial healing has begun. The patient pays the price when meticulous tech-

nique is exercised during the intra-abdominal portion of the operation but forgotten when the abdominal wall is closed.

In this monograph, Poole discusses the various methods of wound closure, the process of wound healing, and the causes of wound failure.

The author begins with a brief introduction on wound healing. The detail of this preface is sufficient only to make a valid point: delayed or failed wound healing has very little to do with most dehiscences, and faulty surgical technique is usually the culprit.

Additional insights are then provided by a short review of the epidemiology of dehiscence. Despite innumerable studies on wound closure, the rate of dehiscence following abdominal surgery and its associated mortality remain stable at 0.65% and 20%, respectively. The author points out that the incidence of dehiscence is often underestimated by clinicians because they do not follow up their patients long enough; an early, small fascial separation may not be detected until the later appearance of an incisional hernia.

The monograph then covers the various factors that have been associated with retarded wound healing. Despite the evidence that malnutrition, age, corticosteroid and chemotherapeutic therapies, and other factors do delay wound healing, there is little evidence that any of them promote dehiscence. This is to be expected, as most dehiscences occur early after surgery when little wound healing has taken place.

The factors that most directly affect a wound, ie, surgical technique and suture material, are then discussed in some detail. Experienced surgeons will be familiar with the highlights of this chapter. For example, wound length, position, and direction have little effect on dehiscence as long as the fascial closure is accomplished with adequate bites, minimal tension, and stout suture (interrupted, running, slowly absorbable, or nonabsorbable).

The text then closes with a chapter on the clinical diagnosis of dehiscence and its management.

The serious student of wound healing will be disappointed with this monograph's brevity, the less-than-exhaustive bibliography, and the omission of topics such as the use of prosthetic materials in wound closure. However, the book will provide the medical student and surgical house officer with a sound understanding of dehiscence and its prevention. It will also be an enjoyable review for the experienced surgeon. We as surgeons can all benefit from an occasional reminder that the abdominal wall should be treated with all the respect we show the intra-abdominal organs.

WILLIAM J. PLAUS, MD
Denver

The Art of Surgical Technique, by Milton T. Edgerton, 218 pp, with illus, $41.50, Baltimore, Williams & Wilkins, 1988.

Despite two forewords, a preface, and an introduction, the objective of this book is unclear. The author is a highly respected elder statesman of plastic surgery, and this summary of principles of technique is clearly a labor of love by a thoughtful scholar and gentleman.

The book is comparable in several ways with Dr Ralph Millard's books on plastic surgery, which also contain a mixture of anecdotes, tradition, scientific data, pearls of wisdom, and personal opinions. *The Art of Surgical Technique* is a book to be enjoyed by all of us and one to be studied by medical students considering surgery, surgical residents, surgical assistants, scrub nurses, and technicians. Practicing surgeons, and specifically plastic surgeons, will profit by seeing much of what they do instinctively spelled out, as well as by learning a few new things.

Although it is worth understanding one's professional roots, in this book there is perhaps too much emphasis on outdated instruments and techniques such as freehand skin grafting knives and drum dermatomes. Even Barton dressings for jaw fractures are mentioned. Some modern techniques and materials, such as skin staples, lasers, and monofilament absorbable suture, are omitted. Surgical dogma inserted without scientific support is at least worthy of an opposing viewpoint. Use of antibiotic irrigation and topical thrombotic agents are two examples. Holding suture needles at the end and using drains to prevent hematomas are two other controversial techniques.

Dr Edgerton admits his biases, and I could imagine my knuckles being rapped if I violated them as a surgical resident. The "suction cannula . . . is an instrument of the devil"; "a quiet operating room improves the quality of surgery"; "sponging . . . is often done badly by surgeons or their assistants." Such aphorisms are instructive and add charm.

I applaud the emphasis on the nearly lost arts of surgical assisting and scrub nursing. Hand signals for silent passing of instruments are described in detail. Such gentlemanly concern with the technique of dignified and efficient interaction between the surgeon and his or her assistants makes this a unique contribution. There is also an excellent section on the art (and underlying science) of dressings and wound care. As anticipated from a surgeon nurtured in the halstedian tradition, atraumatic handling of tissues is repeatedly emphasized.

This is not a long book and, in common with many modern surgical texts, it contains much blank space and repeated figures, although the illustrations are very nicely done. *The Art of Surgical Technique* can be read and enjoyed in a night or two and will make a valued gift to a special resident or assistant, as well as contributing to the body of surgical literature.

In intra-abdominal and gynecologic infection due to indicated organisms

CEFOTAN® IM/IV (cefotetan disodium)

Does so much for so much less than cefoxitin

For Intravenous or Intramuscular Use
BRIEF SUMMARY

INDICATIONS AND USAGE
TREATMENT: CEFOTAN® (cefotetan disodium) is indicated for the therapeutic treatment of the following infections when caused by susceptible strains of the designated organisms:
Urinary tract infections caused by *E coli, Klebsiella* species (including *K pneumoniae*), *Proteus mirabilis* and *Proteus* sp (which may include the organisms now called *Proteus vulgaris, Providencia rettgeri*, and *Morganella morganii*).
Lower respiratory tract infections caused by *Streptococcus pneumoniae* (formerly *D pneumoniae*), *Staphylococcus aureus* (penicillinase- and nonpenicillinase-producing strains), *Haemophilus influenzae* (including ampicillin-resistant strains), *Klebsiella* species (including *K pneumoniae*), and *E coli*.
Skin and skin structure infections caused by *Staphylococcus aureus* (penicillinase- and nonpenicillinase-producing strains), *Staphylococcus epidermidis,* Streptococcus pyogenes* and *Streptococcus* species (excluding enterococci), and *E coli*.
Gynecologic infections caused by *Staphylococcus aureus*† (including penicillinase- and nonpenicillinase-producing strains), *Staphylococcus epidermidis,* Streptococcus* species (excluding enterococci), *E coli, Proteus mirabilis, Neisseria gonorrhoeae, Bacteroides* species (excluding *B distasonis, B ovatus, B thetaiotaomicron*), *Fusobacterium* species,† and gram-positive anaerobic cocci (including *Peptococcus* and *Peptostreptococcus* species†).
Intra-abdominal infections caused by *E coli, Klebsiella* species (including *K pneumoniae*†), *Streptococcus* species (excluding enterococci), and *Bacteroides* species (excluding *B distasonis, B ovatus, B thetaiotaomicron*).
Bone and joint infections caused by *Staphylococcus aureus*.†
***NOTE:** Some strains of *Staphylococcus epidermidis* are resistant to cefotetan.
† Efficacy for this organism in this organ system was studied in fewer than ten infections.
PROPHYLAXIS: The preoperative administration of CEFOTAN may reduce the incidence of certain postoperative infections in patients undergoing surgical procedures that are classified as clean contaminated or potentially contaminated (eg, cesarean section, abdominal or vaginal hysterectomy, transurethral surgery, biliary tract surgery, and gastrointestinal surgery).

The prophylactic dose of CEFOTAN should be administered 30 to 60 minutes prior to surgery. In patients undergoing cesarean section, CEFOTAN should be administered intravenously after the clamping of the umbilical cord.

If there are signs and symptoms of infection, specimens for culture should be obtained for identification of the causative organism so that appropriate therapeutic measures may be initiated.

CONTRAINDICATIONS
CEFOTAN is contraindicated in patients with known allergy to the cephalosporin group of antibiotics.

WARNINGS
Before therapy with CEFOTAN is instituted, careful inquiry should be made to determine whether the patient has had previous hypersensitivity reactions to cefotetan disodium, cephalosporins, penicillins, or other drugs. This product should be given cautiously to penicillin-sensitive patients. Antibiotics should be administered with caution to any patient who has demonstrated some form of allergy, particularly to drugs. If an allergic reaction to CEFOTAN occurs, discontinue the drug. Serious acute hypersensitivity reactions may require epinephrine and other emergency measures.

Pseudomembranous colitis has been reported with the use of cephalosporins (and other broad-spectrum antibiotics); therefore, it is important to consider its diagnosis in patients who develop diarrhea in association with antibiotic use.

Treatment with broad-spectrum antibiotics may alter normal flora of the colon and may permit overgrowth of clostridia. Studies indicate a toxin produced by *Clostridium difficile* is one primary cause of antibiotic-associated colitis. Cholestyramine and colestipol resins have been shown to bind the toxin in vitro.

Mild cases of colitis may respond to drug discontinuance alone. Moderate to severe cases should be managed with fluid, electrolyte, and protein supplementation as indicated. When the colitis is not relieved by drug discontinuance, or when it is severe, oral vancomycin is the treatment of choice for antibiotic-associated pseudomembranous colitis produced by *C difficile*. Other causes should also be considered.

PRECAUTIONS
GENERAL: As with other broad-spectrum antibiotics, prolonged use of CEFOTAN may result in overgrowth of nonsusceptible organisms. Careful observation of the patient is essential. If superinfection does occur during therapy, appropriate measures should be taken.

In common with many other broad-spectrum antibiotics, CEFOTAN may be associated with a fall in prothrombin activity. Those at risk include patients with renal or hepatic impairment, or poor nutritional state. Prothrombin times should be monitored in patients at risk and exogenous Vitamin K administered as indicated.

CEFOTAN should be used with caution in individuals with a history of gastrointestinal disease, particularly colitis.

INFORMATION FOR PATIENTS: As with some other cephalosporins, a disulfiram-like reaction characterized by flushing, sweating, headache, and tachycardia may occur when alcohol (beer, wine, etc) is ingested within 72 hours after CEFOTAN administration. Patients should be cautioned about the ingestion of alcoholic beverages following the administration of CEFOTAN.

DRUG INTERACTIONS: If CEFOTAN and an aminoglycoside are used concomitantly, renal function should be carefully monitored, especially if higher dosages of the aminoglycoside are to be administered or if therapy is prolonged, because of the potential nephrotoxicity and ototoxicity of aminoglycoside antibiotics. Although, to date, nephrotoxicity has not been noted when CEFOTAN was given alone, it is possible that nephrotoxicity may be potentiated if CEFOTAN is used concomitantly with an aminoglycoside.

DRUG/LABORATORY TEST INTERACTIONS: A false positive reaction for glucose in urine may occur with Benedict's or Fehling's solution.

As with other cephalosporins, high concentrations of cefotetan may interfere with measurement of serum and urine creatinine levels of Jaffe reaction and produce false increases in the levels of creatinine reported.

CARCINOGENESIS, MUTAGENESIS, IMPAIRMENT OF FERTILITY: Although long-term studies in animals have not been performed to evaluate carcinogenic potential, no mutagenic potential of cefotetan was found in standard laboratory tests.

Cefotetan has adverse effects on the testes of prepubertal rats. Subcutaneous administration of 500 mg/kg/day (approx 8-16 times the usual adult human dose) on days 6-35 of life (thought to be de-

CEFOTAN® (cefotetan disodium)

velopmentally analogous to late childhood and prepuberty in humans) resulted in reduced testicular weight and seminiferous tubule degeneration in 10 of 10 animals. Affected cells included spermatogonia and spermatocytes; Sertoli and Leydig cells were unaffected. Incidence and severity of lesions were dose-dependent; at 120 mg/kg/day (approx 2-4 times the usual human dose), only 1 of 10 treated animals was affected, and the degree of degeneration was mild. Similar lesions have been observed in experiments of comparable design with other methylthiotetrazole-containing antibiotics and impaired fertility has been reported, particularly at high dose levels. No testicular effects were observed in 7-week-old rats treated with up to 1000 mg/kg/day SC for 5 weeks, or in infant dogs (3 weeks old) that received up to 300 mg/kg/day IV for 5 weeks. The relevance of these findings to humans is unknown.

USAGE IN PREGNANCY: Pregnancy Category B: Reproduction studies have been performed in rats and monkeys at doses up to 20 times the human dose and have revealed no evidence of impaired fertility or harm to the fetus due to cefotetan. There are, however, no adequate and well-controlled studies in pregnant women. Because animal reproductive studies are not always predictive of human response, this drug should be used during pregnancy only if clearly needed.

USAGE IN NURSING MOTHERS: Cefotetan is excreted in human milk in very low concentrations. Caution should be exercised when cefotetan is administered to a nursing woman.

PEDIATRIC USE: Safety and effectiveness in children have not been established.

ADVERSE REACTIONS
In clinical studies the following adverse effects were considered related to CEFOTAN therapy.
Gastrointestinal symptoms occurred in 1.5 percent of patients; the most frequent were diarrhea (1 in 80) and nausea (1 in 700).
Hematologic laboratory abnormalities occurred in 1.4 percent of patients and included eosinophilia (1 in 200), positive direct Coombs' test (1 in 250), and thrombocytosis (1 in 300).
Hepatic enzyme elevations occurred in 1.2 percent of patients and included a rise in SGPT (1 in 150), SGOT (1 in 300), alkaline phosphatase (1 in 700), and LDH (1 in 700).
Hypersensitivity reactions were reported in 1.2 percent of patients and included rash (1 in 150) and itching (1 in 700).
Local effects were reported in less than one percent of patients and included phlebitis at the site of injection (1 in 300), and discomfort (1 in 500).

DOSAGE AND ADMINISTRATION
TREATMENT: The usual adult dosage is 1 or 2 grams of CEFOTAN administered intravenously or intramuscularly every 12 hours for 5 to 10 days. Proper dosage and route of administration should be determined by the condition of the patient, severity of the infection, and susceptibility of the causative organism.

GENERAL GUIDELINES FOR DOSAGE OF CEFOTAN

Type of Infection	Daily Dose	Frequency and Route
Urinary Tract	1-4 grams	500 mg every 12 hours IV or IM 1 or 2 g every 24 hours IV or IM 1 or 2 g every 12 hours IV or IM
Other Sites	2-4 grams	1 or 2 g every 12 hours IV or IM
Severe	4 grams	2 g every 12 hours IV
Life-Threatening	6* grams	3 g every 12 hours IV

*Maximum daily dosage should not exceed 6 grams.

PROPHYLAXIS: To prevent postoperative infection in clean contaminated or potentially contaminated surgery in adults, the recommended dosage is 1 or 2 g of CEFOTAN administered once, intravenously, 30 to 60 minutes prior to surgery. In patients undergoing cesarean section, the dose should be administered as soon as the umbilical cord is clamped.

IMPAIRED RENAL FUNCTION: When renal function is impaired, a reduced dosage schedule must be employed. The following dosage guidelines may be used.

DOSAGE GUIDELINES FOR PATIENTS WITH IMPAIRED RENAL FUNCTION

Creatinine Clearance mL/min	Dose	Frequency
>30	Usual Recommended Dose*	Every 12 hours
10-30	Usual Recommended Dose*	Every 24 hours
<10	Usual Recommended Dose*	Every 48 hours

*Dose determined by the type and severity of infection, and susceptibility of the causative organism.

Cefotetan is dialyzable and it is recommended that for patients undergoing intermittent hemodialysis, one-quarter of the usual recommended dose be given every 24 hours on days between dialysis and one-half the usual recommended dose on the day of dialysis.

HOW SUPPLIED
CEFOTAN is a dry, white to pale yellow powder supplied in vials containing cefotetan disodium equivalent to 1 g and 2 g cefotetan activity for intravenous and intramuscular administration. The 1 g dose is available in 10 mL and 100 mL vials, and the 2 g dose is available in 20 mL and 100 mL vials. The vials should not be stored at temperatures above 22°C and should be protected from light.
1 g in 10 mL vial (NDC 0038-0376-10); 2 g in 20 mL vial (NDC 0038-0377-20); 1 g in 100 mL vial (NDC 0038-0376-11); 2 g in 100 mL vial (NDC 0038-0377-21)

Rocephin® IV·IM

ceftriaxone sodium/Roche

Before prescribing, please consult complete product information, a summary of which follows:

INDICATIONS AND USAGE: Rocephin is indicated for the treatment of the following infections when caused by susceptible organisms:

LOWER RESPIRATORY TRACT INFECTIONS caused by *Strep. pneumoniae, Streptococcus* species (excluding enterococci), *Staph. aureus, H. influenzae, H. parainfluenzae, Klebsiella* species (including *K. pneumoniae*), *E. coli, E. aerogenes, Proteus mirabilis* and *Serratia marcescens*.

SKIN AND SKIN STRUCTURE INFECTIONS caused by *Staph. aureus, Staph. epidermidis, Streptococcus* species (excluding enterococci), *E. cloacae, Klebsiella* species (including *K. pneumoniae*), *Proteus mirabilis* and *Pseudomonas aeruginosa*.

URINARY TRACT INFECTIONS (complicated and uncomplicated) caused by *E. coli, Proteus mirabilis, Proteus vulgaris, M. morganii* and *Klebsiella* species (including *K. pneumoniae*).

UNCOMPLICATED GONORRHEA (cervical/urethral and rectal) caused by *Neisseria gonorrhoeae*, including both penicillinase and nonpenicillinase producing strains.

PELVIC INFLAMMATORY DISEASE caused by *N. gonorrhoeae*.

BACTERIAL SEPTICEMIA caused by *Staph. aureus, Strep. pneumoniae, E. coli, H. influenzae* and *K. pneumoniae*.

BONE AND JOINT INFECTIONS caused by *Staph. aureus, Strep. pneumoniae, Streptococcus* species (excluding enterococci), *E. coli, P. mirabilis, K. pneumoniae* and *Enterobacter* species.

INTRA-ABDOMINAL INFECTIONS caused by *E. coli* and *K. pneumoniae*.

MENINGITIS caused by *H. influenzae, N. meningitidis* and *Strep. pneumoniae*. Ceftriaxone has also been used successfully in a limited number of cases of meningitis and shunt infections caused by *Staph. epidermidis* and *E. coli*.

SURGICAL PROPHYLAXIS: Preoperative administration of a single 1 gm dose may reduce incidence of postoperative infections in patients undergoing surgical procedures classified as contaminated or potentially contaminated (*e.g.*, vaginal or abdominal hysterectomy) and in those for whom infection at the operative site presents serious risk (*e.g.*, during coronary artery bypass surgery).

Although ceftriaxone has been shown to have been as effective as cefazolin in the prevention of infection following coronary artery bypass surgery, no placebo-controlled trials have been conducted to evaluate any cephalosporin antibiotic in the prevention of infection following coronary artery bypass surgery. When administered before indicated surgical procedures, a single 1 gm dose provides protection from most infections due to susceptible organisms for duration of procedure.

SUSCEPTIBILITY TESTING: Before instituting treatment with Rocephin, appropriate specimens should be obtained for isolation of the causative organism and for determination of its susceptibility to the drug. Therapy may be instituted prior to obtaining results of susceptibility testing.

CONTRAINDICATIONS: Rocephin is contraindicated in patients with known allergy to the cephalosporin class of antibiotics.

WARNINGS: BEFORE THERAPY WITH ROCEPHIN IS INSTITUTED, CAREFUL INQUIRY SHOULD BE MADE TO DETERMINE WHETHER THE PATIENT HAS HAD PREVIOUS HYPERSENSITIVITY REACTIONS TO CEPHALOSPORINS, PENICILLINS OR OTHER DRUGS. THIS PRODUCT SHOULD BE GIVEN CAUTIOUSLY TO PENICILLIN-SENSITIVE PATIENTS. ANTIBIOTICS SHOULD BE ADMINISTERED WITH CAUTION TO ANY PATIENT WHO HAS DEMONSTRATED SOME FORM OF ALLERGY, PARTICULARLY TO DRUGS. SERIOUS ACUTE HYPERSENSITIVITY REACTIONS MAY REQUIRE THE USE OF SUBCUTANEOUS EPINEPHRINE AND OTHER EMERGENCY MEASURES.

Pseudomembranous colitis has been reported with the use of cephalosporins (and other broad-spectrum antibiotics); therefore, it is important to consider its diagnosis in patients who develop diarrhea in association with antibiotic use.

Treatment with broad-spectrum antibiotics alters the normal flora of the colon and may permit overgrowth of clostridia. Studies indicate a toxin produced by *Clostridium difficile* is one primary cause of antibiotic-associated colitis. Cholestyramine and colestipol resins have been shown to bind to the toxin *in vitro*.

Mild cases of colitis respond to drug discontinuance alone. Moderate to severe cases should be managed with fluid, electrolyte and protein supplementation as indicated.

When the colitis is not relieved by drug discontinuance or when it is severe, oral vancomycin is the treatment of choice for antibiotic-associated pseudomembranous colitis produced by *C. difficile*. Other causes of colitis should also be considered.

Rarely, shadows suggesting sludge have been detected by sonograms of the gallbladder in asymptomatic and symptomatic patients. This appears to be reversible on discontinuation of therapy. In a few symptomatic patients receiving higher than usual doses, who underwent surgery, sludge containing traces of ceftriaxone was recovered from surgical specimens. Discontinue therapy in patients who develop signs or symptoms suggestive of gallbladder disease; consider conservative management.

PRECAUTIONS: *GENERAL:* Although transient elevations of BUN and serum creatinine have been observed, at the recommended dosages, the nephrotoxic potential of Rocephin is similar to that of other cephalosporins.

Ceftriaxone is excreted via both biliary and renal excretion (see Clinical Pharmacology). Therefore, patients with renal failure normally require no adjustment in dosage when usual doses of Rocephin are administered, but concentrations of drug in the serum should be monitored periodically. If evidence of accumulation exists, dosage should be decreased accordingly.

Dosage adjustments should not be necessary in patients with hepatic dysfunction; however, in patients with both hepatic dysfunction and significant renal disease, Rocephin dosage should not exceed 2 gm daily without close monitoring of serum concentrations.

Alterations in prothrombin times have occurred rarely in patients treated with Rocephin. Patients with impaired vitamin K synthesis or low vitamin K stores (*e.g.*, chronic hepatic disease and malnutrition) may require monitoring of prothrombin time during Rocephin treatment. Vitamin K administration (10 mg weekly) may be necessary if the prothrombin time is prolonged before or during therapy.

Prolonged use of Rocephin may result in overgrowth of nonsusceptible organisms. Careful observation of the patient is essential. If superinfection occurs during therapy, appropriate measures should be taken.

Rocephin should be prescribed with caution in individuals with a history of gastrointestinal disease, especially colitis.

CARCINOGENESIS, MUTAGENESIS, IMPAIRMENT OF FERTILITY: Carcinogenesis: Considering the maximum duration of treatment and the class of the compound, carcinogenicity studies with ceftriaxone in animals have not been performed. The maximum

ROCEPHIN® (ceftriaxone sodium/Roche)

duration of animal toxicity studies was six months.

Mutagenesis: Genetic toxicology tests included the Ames test, a micronucleus test and a test for chromosomal aberrations in human lymphocytes cultured *in vitro* with ceftriaxone. Ceftriaxone showed no potential for mutagenic activity in these studies.

Impairment of Fertility: Ceftriaxone produced no impairment of fertility when given intravenously to rats at daily doses up to 586 mg/kg/day, approximately 20 times the recommended clinical dose of 2 gm/day.

PREGNANCY: Teratogenic Effects: Pregnancy Category B. Reproductive studies have been performed in mice and rats at doses up to 20 times the usual human dose and have no evidence of embryotoxicity, fetotoxicity or teratogenicity. In primates, no embryotoxicity or teratogenicity was demonstrated at a dose approximately three times the human dose. There are, however, no adequate and well-controlled studies in pregnant women. Because animal reproductive studies are not always predictive of human response, this drug should be used during pregnancy only if clearly needed.

Nonteratogenic Effects: In rats, in the Segment I (fertility and general reproduction) and Segment III (perinatal and postnatal) studies with intravenously administered ceftriaxone, no adverse effects were noted on various reproductive parameters during gestation and lactation, including postnatal growth, functional behavior and reproductive ability of the offspring, at doses of 586 mg/kg/day or less.

NURSING MOTHERS: Low concentrations of ceftriaxone are excreted in human milk. Caution should be exercised when Rocephin is administered to a nursing woman.

PEDIATRIC USE: Safety and effectiveness of Rocephin in neonates, infants and children have been established for the dosages described in the Dosage and Administration section. *In vitro* studies have shown ceftriaxone, like some other cephalosporins, can displace bilirubin from serum albumin. Exercise caution before administration to hyperbilirubinemic neonates, especially prematures.

ADVERSE REACTIONS: Rocephin is generally well tolerated. In clinical trials, the following adverse reactions, which were considered to be related to Rocephin therapy or of uncertain etiology, were observed:

LOCAL REACTIONS—pain, induration or tenderness at the site of injection (1%). Less frequently reported (less than 1%) was phlebitis after I.V. administration.

HYPERSENSITIVITY—rash (1.7%). Less frequently reported (less than 1%) were pruritus, fever or chills.

HEMATOLOGIC—eosinophilia (6%), thrombocytosis (5.1%) and leukopenia (2.1%). Less frequently reported (less than 1%) were anemia, neutropenia, lymphopenia, thrombocytopenia and prolongation of the prothrombin time.

GASTROINTESTINAL—diarrhea (2.7%). Less frequently reported (less than 1%) were nausea or vomiting, and dysgeusia.

HEPATIC—elevations of SGOT (3.1%) or SGPT (3.3%). Less frequently reported (less than 1%) were elevations of alkaline phosphatase and bilirubin.

RENAL—elevations of the BUN (1.2%). Less frequently reported (less than 1%) were elevations of creatinine and the presence of casts in the urine.

CENTRAL NERVOUS SYSTEM—headache or dizziness were reported occasionally (less than 1%).

GENITOURINARY—moniliasis or vaginitis were reported occasionally (less than 1%).

MISCELLANEOUS—diaphoresis and flushing were reported occasionally (less than 1%).

Other rarely observed adverse reactions (less than 0.1%) include leukocytosis, lymphocytosis, monocytosis, basophilia, a decrease in the prothrombin time, jaundice, gallbladder sludge, glycosuria, hematuria, anaphylaxis, bronchospasm, serum sickness, abdominal pain, colitis, flatulence, dyspepsia, palpitations and epistaxis.

DOSAGE AND ADMINISTRATION: Rocephin may be administered intravenously or intramuscularly. The usual adult daily dose is 1 to 2 gm given once a day (or in equally divided doses twice a day) depending on the type and severity of the infection. The total daily dose should not exceed 4 grams.

For the treatment of serious miscellaneous infections in children, other than meningitis, the recommended total daily dose is 50 to 75 mg/kg (not to exceed 2 grams), given in divided doses every 12 hours.

Generally, Rocephin therapy should be continued for at least two days after the signs and symptoms of infection have disappeared. The usual duration is 4 to 14 days; in complicated infections longer therapy may be required.

In the treatment of meningitis, a daily dose of 100 mg/kg (not to exceed 4 grams), given in divided doses every 12 hours, should be administered with or without a loading dose of 75 mg/kg.

For the treatment of uncomplicated gonococcal infections, a single intramuscular dose of 250 mg is recommended.

For preoperative use (surgical prophylaxis), a single dose of 1 gm administered 1/2 to 2 hours before surgery is recommended.

When treating infections caused by *Streptococcus pyogenes*, therapy should be continued for at least ten days.

No dosage adjustment is necessary for patients with impairment of renal or hepatic function; however, blood levels should be monitored in patients with severe renal impairment (*e.g.*, dialysis patients) and in patients with both renal and hepatic dysfunctions.

HOW SUPPLIED: Rocephin (ceftriaxone sodium/Roche) is supplied as a sterile crystalline powder in glass vials and piggyback bottles. The following packages are available:

Vials containing 250 mg, 500 mg, 1 gm or 2 gm equivalent of ceftriaxone; piggyback bottles containing 1 gm or 2 gm equivalent of ceftriaxone; bulk pharmacy containers containing 10 gm equivalent of ceftriaxone (NOT FOR DIRECT ADMINISTRATION).

Also supplied as a sterile crystalline powder as follows:
ADD-Vantage Vials** containing 1 gm or 2 gm equivalent of ceftriaxone.

Also supplied premixed as a frozen iso-osmotic, sterile, nonpyrogenic solution of ceftriaxone sodium in 50 mL single dose plastic containers,† as follows:

1 gm equivalent of ceftriaxone, iso-osmotic with approximately 1.9 gm dextrose hydrous, USP added.

2 gm equivalent of ceftriaxone, iso-osmotic with approximately 1.2 gm dextrose hydrous, USP added.

NOTE: Rocephin in the frozen state should not be stored above -20°C.

General Surgeons

The Department of Surgery at the University of Massachusetts Medical Center is seeking one or more broadly trained surgeons to teach and provide general surgical care, while devoting particular emphasis to development of a specialized field of surgery, such as oncology, endoscopy, biliary lithotripsy, or colon and rectal surgery. Applicants should send C.V.'s and direct their inquiries to Dr. H. Brownell Wheeler, Professor and Chairman, Department of Surgery, University of Massachusetts Medical Center, 55 Lake Avenue North, Worcester MA 01655. An equal opportunity/affirmative action employer.

UNIVERSITY OF MASSACHUSETTS MEDICAL CENTER

ORTHOPEDIC SURGEON

Office based, full or part time. No surgery, no night call. Sound clinical judgment and California licensure essential. Send CV to Medical Director, Bay Shores Medical Group, Inc., 502 Torrance Blvd., Redondo Beach, CA 90277.

FLORIDA, OKLAHOMA

General Surgery Opportunities

FLORIDA: Gainesville-based regional multi-hospital Healthcare System has immediate need for BE/BC general surgeons. Paid malpractice, salary guarantee, office space, moving expenses, others.

OKLAHOMA: BE/BC general surgeon needed to join multi-specialty group. Fee-for-service practice. Progressive, thriving, family oriented community. Excellent income potential and relocation package.

CHAIR DEPARTMENT OF SURGERY UNIVERSITY OF TEXAS SOUTHWESTERN MEDICAL CENTER AT DALLAS

The University of Texas Southwestern Medical Center at Dallas is seeking a chair for the Department of Surgery. Candidates should be board certified and have extensive clinical, academic, and administrative experience. The Chair of Surgery is also Chief of Surgery at Parkland Memorial Hospital as well as the University Medical Center which is scheduled to open in late 1989. The department also is responsible for providing surgical services at the 1000-bed Dallas Veterans Hospital. Important responsibilities include direction of the residency training program, medical student teaching, and further development of clinical and basic research.

Send curriculum vitae to: F. Gary Cunningham, M.D., Professor and Chairman, Department of Obstetrics & Gynecology, Chairman, Surgery Search Committee, University of Texas Southwestern Medical Center at Dallas, 5323 Harry Hines Boulevard, Dallas, Texas 75235-9032.

An Affirmative Action/ Equal Opportunity Employer.

vicodin® C-III

(hydrocodone bitartrate 5 mg [Warning: May be habit forming] and acetaminophen 500 mg)

INDICATIONS AND USAGE: For the relief of moderate to moderately severe pain.
CONTRAINDICATIONS: Hypersensitivity to acetaminophen or hydrocodone.
WARNINGS:
Allergic-Type Reaction: VICODIN contains sodium metabisulfite, a sulfite that may cause allergic-type reactions including anaphylactic symptoms and life-threatening or less severe asthmatic episodes in certain susceptible people. The overall prevalence of sulfite sensitivity in the general population is unknown and probably low. Sulfite sensitivity is seen more frequently in asthmatic than non-asthmatic people.
Respiratory Depression: At high doses or in sensitive patients, hydrocodone may produce dose-related respiratory depression by acting directly on brain stem respiratory centers. Hydrocodone also affects centers that control respiratory rhythm, and may produce irregular and periodic breathing. If significant respiratory depression occurs, it may be antagonized by the use of naloxone hydrochloride. (see ADVERSE REACTIONS: Respiratory Depression).
Head Injury and Increased Intracranial Pressure: The respiratory depressant effects of narcotics and their capacity to elevate cerebrospinal fluid pressure may be markedly exaggerated in the presence of head injury, other intracranial lesions or a preexisting increase in intracranial pressure. Furthermore, narcotics produce adverse reactions which may obscure the clinical course of patients with head injuries.
Acute Abdominal Conditions: The administration of narcotics may obscure the diagnosis or clinical course of patients with acute abdominal conditions.
PRECAUTIONS:
Special Risk Patients: As with any narcotic analgesic agent, VICODIN should be used with caution in elderly or debilitated patients and those with severe impairment of hepatic or renal function, hypothyroidism, Addison's disease, prostatic hypertrophy or urethral stricture. The usual precautions should be observed and the possibility of respiratory depression should be kept in mind.
Information for Patients: VICODIN, like all narcotics, may impair the mental and/or physical abilities required for the performance of potentially hazardous tasks such as driving a car or operating machinery; patients should be cautioned accordingly.
Cough Reflex: Hydrocodone suppresses the cough reflex; as with all narcotics, caution should be exercised when VICODIN is used postoperatively and in patients with pulmonary disease.
Drug Interactions: Patients receiving other narcotic analgesics, antipsychotics, antianxiety agents, or other CNS depressants (including alcohol) concomitantly with VICODIN may exhibit an additive CNS depression. When combined therapy is contemplated, the dose of one or both agents should be reduced. The use of MAO inhibitors or tricyclic antidepressants with hydrocodone preparations may increase the effect of either the antidepressant or hydrocodone. The concurrent use of anticholinergics with hydrocodone may produce paralytic ileus.
Usage in Pregnancy: Pregnancy Category C. Hydrocodone has been shown to be teratogenic in hamsters when given in doses 700 times the human dose. There are no adequate and well-controlled studies in pregnant women. VICODIN should be used during pregnancy only if the potential benefit justifies the potential risk to the fetus.
Nonteratogenic effects: Babies born to mothers who have been taking opioids regularly prior to delivery will be physically dependent. The withdrawal signs include irritability and excessive crying, tremors, hyperactive reflexes, increased respiratory rate, increased stools, sneezing, yawning, vomiting, and fever. The intensity of the syndrome does not always correlate with the duration of material opioid use or dose. There is no consensus on the best method of managing withdrawal. Chlorpromazine 0.7 to 1.0 mg/kg q6h, and paregoric 2 to 4 drops/kg q4h, have been used to treat withdrawal symptoms in infants. The duration of therapy is 4 to 28 days, with the dosage decreased as tolerated.
Labor and Delivery: As with all narcotics, administration of VICODIN to the mother shortly before delivery may result in some degree of respiratory depression in the newborn, especially if higher doses are used.
Nursing Mothers: It is not known whether this drug is excreted in human milk. Because many drugs are excreted in human milk and because of the potential for serious adverse reactions in nursing infants from VICODIN, a decision should be made whether to discontinue nursing or to discontinue the drug, taking into account the importance of the drug to the mother.
Pediatric Use: Safety and effectiveness in children have not been established.
ADVERSE REACTIONS:
Central Nervous System: Sedation, drowsiness, mental clouding, lethargy, impairment of mental and physical performance, anxiety, fear, dysphoria, dizziness, psychic dependence, mood changes.
Gastrointestinal System: Nausea and vomiting may occur; they are more frequent in ambulatory than in recumbent patients. The antiemetic phenothiazines are useful in suppressing these effects; however, some phenothiazine derivatives seem to be antianalgesic and to increase the amount of narcotic required to produce pain relief, while other phenothiazines reduce the amount of narcotic required to produce a given level of analgesia. Prolonged administration of VICODIN may produce constipation.
Genitourinary System: Ureteral spasm, spasm of vesical sphincters and urinary retention have been reported.
Respiratory Depression: (See WARNINGS.)
DOSAGE AND ADMINISTRATION: Dosage should be adjusted according to the severity of the pain and the response of the patient. However, tolerance to hydrocodone can develop with continued use and the incidence of untoward effects is dose related.
The usual adult dosage is one or two tablets every four to six hours as needed for pain. The total 24 hour dose should not exceed 8 tablets.

Revised June, 1987 5803

knoll®

Freedom from pain

Just one part of pain relief therapy.

Vicodin provides exceptional patient acceptance– 700 million doses in ten years.

- In ten years of clinical experience, nausea, sedation or constipation have rarely been reported.[1]

...and longer lasting pain relief– up to 6 hours.

- Vicodin contains hydrocodone not codeine. In one study, 10 mg of hydrocodone alone wa shown to be as effective as 60 mg of codeine.[2]
- In a double-blind study, Vicodin (2 tablets), provided longer lasting pain relief than 60 mg of codeine.[3]

Plus...

- Vicodin offers the convenience of CIII prescribing.
- Dosage flexibility – 1 tablet every 4 to 6 hours or 2 tablets every 4 to 6 hours (up to 8 tablets in 24 hours).

ORIGINAL ARTICLES

Evaluation of Prostacyclin Production by Human Gallbladder 277
Donald L. Kaminski, MD; Y. G. Deshpande, MS; Scott Westfall, MD; David Herbold, MD, St Louis, Mo
- Prostacyclin formation may be an important mediator of the inflammatory changes of cholecystitis.

The Efficacy of Oral Antimicrobials in Reducing Aerobic and Anaerobic Colonic Mucosal Flora 281
Jonathan I. Groner, MD; Charles E. Edmiston, Jr, PhD; Candace J. Krepel; Gordon L. Telford, MD; Robert E. Condon, MD, MS, Milwaukee, Wis
- Oral antibiotics with mechanical cleansing, but not mechanical preparation alone, decreased mucosa-associated bacteria.

Emergency Abdominal Operations in the Patient With Acquired Immunodeficiency Syndrome 285
Joshua H. Burack, MD; Marc S. Mandel, MD; Lawrence S. Bizer, MD, Bronx, NY
- Mortality rate was high following emergency intra-abdominal operations in AIDS patients.

Errors in Estimating Energy Expenditure in Critically Ill Surgical Patients 287
Vincente Cortes, MD, Miami, Fla, Loren D. Nelson, MD, Nashville, Tenn
- Because of overestimation of the stress factor, calculated or estimated energy expenditure was greater than measured energy expenditure.

Hemostasis of Solid Viscus Trauma by Intraparenchymal Injection of Fibrin Glue 291
Carl J. Hauser, MD, Los Angeles, Calif
- Intraparenchymal hepatic fibrin glue injection was a more effective hemostatic agent than was topical fibrin glue.

Neutron Therapy for Nonresectable Radioresistant Tumors 294
Lionel Cohen, MD, Frank R. Hendrickson, MD, Batavia, Ill
- High-energy fast neutron beams are a valuable adjunct to manage some tumors that are resistant to conventional therapy.

Gallbladder Response to Enteral Lipids in Injured Patients 301
Ronald C. Merrell, MD; Priscilla Miller-Crotchett, RN; Patricia Lowry, MD, Houston, Tex
- After injury these patients had modest enlargement and diminished contractions of the gallbladder that were not improved with enteral lipids.

Gastric Adenocarcinoma: A Disease in Transition 303
Blake Cady, MD, Boston; Ricardo L. Rossi, MD, Mark L. Silverman, MD, Burlington, Mass; William Piccione, MD, Chicago, Ill; Thomas A. Heck, MD, Dayton, Ohio
- Twenty-seven (47%) of 57 patients who underwent resection for cure survived five years.

Is Extensive Lymphadenectomy Necessary for Surgical Treatment of Intramucosal Carcinoma of the Stomach? 309
Keiji Iriyama, MD; Toyomatsu Asakawa, MD; Hiroshi Koike, MD; Hiroshi Nishiwake, MD; Hiroshi Suzuki, MD, Tsu, Japan
- Lymph node metastases are unlikely in patients with protruding, intramucosal intestinal type gastric carcinomas less than 5 cm in size.

DNA Ploidy and Tumor Invasion in Human Gastric Cancer: Histopathologic Differentiation 314
Daisuke Korenaga, MD; Masaru Haraguchi, MD; Takeshi Okamura, MD; Hideo Baba, MD; Atsushi Saito, MD; Keizo Sugimachi, MD, Fukuoka, Japan
- Aneuploid DNA patterns were associated with more aggressive gastric cancer than were diploid DNA profiles.

The **ARCHIVES OF SURGERY** (ISSN 0004-0010) is published monthly by the American Medical Association, 535 N Dearborn St, Chicago, IL 60610, and is an official publication of the Association. Second-class postage paid at Chicago, IL 60610 and at additional mailing office.

SUBSCRIPTION RATES—The subscription rates for the ARCHIVES OF SURGERY are as follows: $50 for one year, $85 for two years in the United States and US possessions; all other countries, one year, $60; two years, $105 for surface delivery. (For expedited air delivery to most countries, add $15 surcharge for one-year subscription, $30 for two years.) Rates for subscriptions for delivery to Japan or South Korea are available through exclusive agents—contact the publisher. ***Special rates for residents and medical students in the United States and US possessions are available.*** Address inquiries to the American Medical Association, Circulation and Fulfillment Division, 535 N Dearborn St, Chicago, IL 60610. Phone: (312)280-7168.

CHANGE OF ADDRESS—POSTMASTER, send all address changes for the ARCHIVES OF SURGERY to Subscription Department, 535 N Dearborn St, Chicago, IL 60610. Notification of address change must be made at least six weeks in advance, include both old and new addresses, a recent mailing label, and your new zip code.

ADVERTISING PRINCIPLES: Each advertisement in this issue has been reviewed and complies with the principles governing advertising in AMA scientific publications. A copy of these principles is available on request. The appearance of advertising in AMA publications is not an AMA guarantee or endorsement of the product or the claims made for the product by the manufacturer.

CONTENTS—Continued

Prophylactic Antibiotherapy in Abdominal Surgery: First- vs Third-Generation Cephalosporins 323
Nelly Rotman, MD, Creteil, France; Jean-Marie Hay, MD, Colombes, France; Françoise Lacaine, MD, Paris, France; Pierre-Louis Fagniez, MD, Creteil, France; Association de Recherche en Chirurgie Cooperative Group, Bois-Colombes, France
• Cephalosporin prophylaxis was helpful in clean operations, in clean contaminated operations, and in patients with general increased risk of infection.

Guidelines for Practical Utilization of Intraoperative Frozen Sections 331
Marianne U. Prey, MD, St Louis, Mo; Thomas Vitale, MD, Melbourne, Fla; Scott A. Martin, MD, St Louis, Mo
• Intraoperative frozen-section interpretation was associated with 0.15% false-positive and 2.8% false-negative diagnosis rates.

Comparison of Antibody Response With Delayed Hypersensitivity in Severely Injured Patients 339
Michael J. Hershman, FRCS; William G. Cheadle, MD; Sarah H. Appel; Christopher D. George, FRCS; Pattie F. Davidson, RN; Karen M. Cost, PhD; Hiram C. Polk, Jr, MD, Louisville, Ky
• Clinical outcome and antibody response were determined by the extent of initial bacterial contamination.

Computed Tomography and Diagnostic Peritoneal Lavage in Blunt Abdominal Trauma: Their Combined Role 344
Paul A. Kearney, Jr, MD; Thomas Vahey, MD; Richard E. Burney, MD; Gary Glazer, MD, Ann Arbor, Mich
• Peritoneal lavage was helpful in detecting injuries missed by computed tomography.

The Training and Utilization of Surgical Physician Assistants: A Retrospective Study 348
Linda Ballard Brandt; Malcolm S. Beinfield, MD; Horace A. Laffaye, MD, Norwalk, Conn; Arthur E. Baue, MD, St Louis, Mo
• A surgical postgraduate training program for physician assistants provided coverage of surgical patients in hospitals without surgical residencies.

Physiologic Effects of Steep Positioning in the Surgical Intensive Care Unit 352
Loren D. Nelson, MD, Hans B. Anderson, RRT, Miami, Fla
• Continuous rotation reversed the adverse effects on oxygenation caused by positional changes.

Nosocomial Abscess: Results of an Eight-Year Prospective Study of 32 284 Operations 356
Mary M. Olson, RN, BSN, Melody O'Connor Allen, MD, Minneapolis, Minn
• Postoperative infection surveillance was associated with a decrease in wound infection and abscess formation rates.

Determinants of Urea Nitrogen Production in Sepsis: Muscle Catabolism, Total Parenteral Nutrition, and Hepatic Clearance of Amino Acids 362
Mauro Pittiruti, MD; John H. Siegel, MD; Gabriele Sganga, MD; Bill Coleman; Charles E. Wiles III, MD; Robert Placko, Baltimore, Md
• Septic patients who survived had strikingly different metabolic alterations from septic patients with multiple organ failure.

Isolated Regional Perfusion in the Treatment of Subungual Melanoma 373
Peter C. Baas, MD; Harald J. Hoekstra, MD, PhD; Heimen Schraffordt Koops, MD, PhD; J. Wolter Oosterhuis, MD, PhD; Jan Oldhoff, MD, PhD, Groningen, the Netherlands
• Regional hyperthermic cytotoxicity drug perfusion prevented local recurrence following amputation for subungual melanoma.

CLINICAL NOTES

Influence of Estrogen Receptors on Survival and Recurrence in Patients With Breast Cancer Without Lymph Node Metastases 377
Hope S. Maki, MD, James L. Hoehn, MD, Marshfield, Wis
• Estrogen receptor status did not adversely affect outcome in lymph node-negative breast cancer patients.

A Foregut Carcinoid Tumor Causing Zollinger-Ellison Syndrome 381
Gordon B. Werbel, MD; Suzanne P. Nelson, MD; Philip G. Robinson, MD; John Anastasi, MD; Raymond J. Joehl, MD; Robert V. Rege, MD, Chicago, Ill
• A benign gastric carcinoid tumor contained gastrin and produced severe peptic ulcer disease.

TECHNIQUE

Fibrin Glue Achieves Hemostasis in Patients With Coagulation Disorders 385
Harry B. Kram, MD; Ragu C. Nathan, MD; Frederick J. Stafford, MD; Arthur W. Fleming, MD; William C. Shoemaker, MD, Los Angeles, Calif
• Fibrin glue is especially useful in patients with parenchymal organ hemorrhage and disordered coagulation.

More confidence in presumptive antibiotic therapy. Prescribing UNASYN presumptively is a step you can take with confidence. UNASYN covers gram-positives (even enterococci), prevalent gram-negatives, and anaerobes: The right combination for most patients with common mixed infections.*

And UNASYN minimizes safety concerns with a reliable penicillin-class profile.[1] (However, UNASYN is contraindicated in penicillin-allergic patients.)

Expect strong support from UNASYN in the mixed infections* you face every day.

"It's still like walking the high wire, but now I have a safety net."

PARTNERS PRACTICING GOOD MEDICINE.

Bring your outstanding surgical skills to the Southern California Permanente Medical Group and experience the freedom to focus on patient work. Not paperwork.

We are an HMO multispecialty group practice — a partnership composed of and managed by SCPMG physicians.

Opportunities exist for board eligible/certified **Surgeons** with a combined practice of Peripheral Vascular and General Surgery.

Consider the advantages: the finest equipment and latest technology; the availability of consultations with other physicians of distinction; and a broad network of exceptional support personnel backed by the resources of one of the nation's leading HMO's.

Our compensation is competitive and benefits are outstanding. They include: professional liability, medical and dental coverage, vacation and sick leave, continuing education, life insurance and retirement plans. **After two years full-time employment, physicians are eligible to be considered for partnership.**

For a physician application, please call (818) 405-3224 or send your curriculum vitae to: Physician Recruitment, Dept. 78E8, Walnut Center, Pasadena, CA 91188-8854.

INDICATIONS AND USAGE

UNASYN is indicated for the treatment of infections due to susceptible strains of the designated microorganisms in the conditions listed below.

Skin and Skin Structure Infections caused by beta-lactamase producing strains of *Staphylococcus aureus*, *Escherichia coli*,* *Klebsiella* spp.* (including *K. pneumoniae**), *Proteus mirabilis*,* *Bacteroides fragilis*,* *Enterobacter* spp.* and *Acinetobacter calcoaceticus*.*

Intra-Abdominal Infections caused by beta-lactamase producing strains of *Escherichia coli*, *Klebsiella* spp. (including *K. pneumoniae**), *Bacteroides* spp. (including *B. fragilis*), and *Enterobacter* spp.*

Gynecological Infections caused by beta-lactamase producing strains of *Escherichia coli*,* and *Bacteroides* spp.* (including *B. fragilis**).

*Efficacy for this organism in this organ system was studied in fewer than 10 infections.

While UNASYN* (ampicillin sodium/sulbactam sodium) is indicated only for the conditions listed above, infections caused by ampicillin-susceptible organisms are also amenable to treatment with UNASYN due to its ampicillin content. Therefore, mixed infections caused by ampicillin-susceptible organisms and beta-lactamase producing organisms susceptible to UNASYN should not require the addition of another antibiotic.

CONTRAINDICATIONS

The use of UNASYN is contraindicated in individuals with a history of hypersensitivity reactions to any of the penicillins.

WARNINGS

SERIOUS AND OCCASIONALLY FATAL HYPERSENSITIVITY (ANAPHYLACTIC) REACTIONS HAVE BEEN REPORTED IN PATIENTS ON PENICILLIN THERAPY. THESE REACTIONS ARE MORE APT TO OCCUR IN INDIVIDUALS WITH A HISTORY OF PENICILLIN HYPERSENSITIVITY AND/OR HYPERSENSITIVITY REACTIONS TO MULTIPLE ALLERGENS. THERE HAVE BEEN INDIVIDUALS WITH A HISTORY OF PENICILLIN HYPERSENSITIVITY WHO HAVE EXPERIENCED SEVERE REACTIONS WHEN TREATED WITH CEPHALOSPORINS. BEFORE THERAPY WITH A PENICILLIN, CAREFUL INQUIRY SHOULD BE MADE CONCERNING PREVIOUS HYPERSENSITIVITY REACTIONS TO PENICILLINS, CEPHALOSPORINS, AND OTHER ALLERGENS. IF AN ALLERGIC REACTION OCCURS, UNASYN SHOULD BE DISCONTINUED AND THE APPROPRIATE THERAPY INSTITUTED.

SERIOUS ANAPHYLACTOID REACTIONS REQUIRE IMMEDIATE EMERGENCY TREATMENT WITH EPINEPHRINE, OXYGEN, INTRAVENOUS STEROIDS, AND AIRWAY MANAGEMENT, INCLUDING INTUBATION, SHOULD ALSO BE ADMINISTERED AS INDICATED.

PRECAUTIONS

General: A high percentage of patients with mononucleosis who receive ampicillin develop a skin rash. Thus, ampicillin class antibiotics should not be administered to patients with mononucleosis. In patients treated with UNASYN the possibility of superinfections with mycotic or bacterial pathogens should be kept in mind during therapy. If superinfections occur (usually involving *Pseudomonas* or *Candida*), the drug should be discontinued and/or appropriate therapy instituted.

Drug Interactions: Probenecid decreases the renal tubular secretion of ampicillin and sulbactam. Concurrent use of probenecid with UNASYN may result in increased and prolonged blood levels of ampicillin and sulbactam. The concurrent administration of allopurinol and ampicillin increases substantially the incidence of rashes in patients receiving both drugs as compared to patients receiving ampicillin alone. It is not known whether this potentiation of ampicillin rashes is due to allopurinol or the hyperuricemia present in these patients. There are no data with UNASYN and allopurinol administered concurrently. UNASYN and aminoglycosides should not be reconstituted together due to the *in vitro* inactivation of aminoglycosides by the ampicillin component of UNASYN.

Drug/Laboratory Test Interactions: Administration of UNASYN will result in high urine concentrations of ampicillin. High urine concentrations of ampicillin may result in false positive reactions when testing for the presence of glucose in urine using Clinitest™, Benedict's Solution or Fehling's Solution. It is recommended that glucose tests based on enzymatic glucose oxidase reactions (such as Clinistix™ or Testape™) be used. Following administration of ampicillin to pregnant women a transient decrease in plasma concentration of total conjugated estriol, estriol glucuronide, conjugated estrone, and estradiol has been noted. This effect may also occur with UNASYN.

Carcinogenesis, Mutagenesis, Impairment of Fertility: Long-term studies in animals have not been performed to evaluate carcinogenic or mutagenic potential.

Pregnancy

Pregnancy Category B: Reproduction studies have been performed in mice, rats, and rabbits at doses up to ten (10) times the human dose and have revealed no evidence of impaired fertility or harm to the fetus due to UNASYN. There are, however, no adequate and well controlled studies in pregnant women. Because animal reproduction studies are not always predictive of human response, this drug should be used during pregnancy only if clearly needed. (See—Drug/Laboratory Test Interactions.)

Labor and Delivery: Studies in guinea pigs have shown that intravenous administration of ampicillin decreased the uterine tone, frequency of contractions, height of contractions, and duration of contractions. However, it is not known whether the use of UNASYN in humans during labor or delivery has immediate or delayed adverse effects on the fetus, prolongs the duration of labor, or increases the likelihood that forceps delivery or other obstetrical intervention or resuscitation of the newborn will be necessary.

Nursing Mothers: Low concentrations of ampicillin and sulbactam are excreted in the milk; therefore, caution should be exercised when UNASYN is administered to a nursing woman.

Pediatric Use: The efficacy and safety of UNASYN have not been established in infants and children under the age of 12.

ADVERSE REACTIONS

UNASYN is generally well tolerated. The following adverse reactions have been reported.

Local Adverse Reactions

Pain at IM injection site—16% Pain at IV injection site—3%
Thrombophlebitis—3%

Systemic Adverse Reactions

The most frequently reported adverse reactions were diarrhea in 3% of the patients and rash in less than 2% of the patients.

Additional systemic reactions reported in less than 1% of the patients were: itching, nausea, vomiting, candidiasis, fatigue, malaise, headache, chest pain, flatulence, abdominal distension, glossitis, urine retention, dysuria, edema, facial swelling, erythema, chills, tightness in throat, substernal pain, epistaxis and mucosal bleeding.

Adverse Laboratory Changes

Adverse laboratory changes without regard to drug relationship that were reported during clinical trials were:

Hepatic: Increased AST (SGOT), ALT (SGPT), alkaline phosphatase, and LDH.

Hematologic: Decreased hemoglobin, hematocrit, RBC, WBC, neutrophils, lymphocytes, platelets and increased lymphocytes, monocytes, basophils, eosinophils, and platelets.

Blood Chemistry: Decreased serum albumin and total proteins.

Renal: Increased BUN and creatinine.

Urinalysis: Presence of RBC's and hyaline casts in urine.

The following adverse reactions have been reported with ampicillin-class antibiotics and can also occur with UNASYN.

Gastrointestinal: Gastritis, stomatitis, black "hairy" tongue, enterocolitis and pseudomembranous colitis.

Hypersensitivity Reactions: Urticaria, erythema multiforme, and an occasional case of exfoliative dermatitis have been reported. These reactions may be controlled with antihistamines and, if necessary, systemic corticosteroids. Whenever such reactions occur, the drug should be discontinued, unless the opinion of the physician dictates otherwise. Serious and occasional fatal hypersensitivity (anaphylactic) reactions can occur with a penicillin (see WARNINGS).

Hematologic: In addition to the adverse laboratory changes listed above for UNASYN, agranulocytosis has been reported during therapy with penicillins. All of these reactions are usually reversible on discontinuation of therapy and are believed to be hypersensitivity phenomena.

ROERIG Pfizer
A division of Pfizer Pharmaceuticals

Nothing comes closer to 100% activity against anaerobes in vitro. It's a fact. Studies have proved no other antibiotic superior to UNASYN in overall antianaerobic activity.[1-10] Not clindamycin. Not metronidazole. Nothing.

And that's nothing to overlook—given the importance of anaerobes in today's mixed infections.

Though clinical results may not always mirror those obtained in vitro, there's a world of confidence in choosing UNASYN for presumptive therapy of the mixed infections* you see every day.

"I used to think only two things in life were certain."

INDICATIONS AND USAGE

UNASYN is indicated for the treatment of infections due to susceptible strains of the designated microorganisms in the conditions listed below.

Skin and Skin Structure Infections caused by beta-lactamase producing strains of *Staphylococcus aureus*, *Escherichia coli*,* *Klebsiella* spp.* (including *K. pneumoniae**), *Proteus mirabilis*,* *Bacteroides fragilis*,* *Enterobacter* spp.,* and *Acinetobacter calcoaceticus*.*

Intra-Abdominal Infections caused by beta-lactamase producing strains of *Escherichia coli*, *Klebsiella* spp. (including *K. pneumoniae**), *Bacteroides* spp. (including *B. fragilis*), and *Enterobacter* spp.*

Gynecological Infections caused by beta-lactamase producing strains of *Escherichia coli*,* and *Bacteroides* spp.* (including *B. fragilis**).

*Efficacy for this organism in this organ system was studied in fewer than 10 infections.

While UNASYN* (ampicillin sodium/sulbactam sodium) is indicated only for the conditions listed above, infections caused by ampicillin-susceptible organisms are also amenable to treatment with UNASYN due to its ampicillin content. Therefore, mixed infections caused by ampicillin-susceptible organisms and beta-lactamase producing organisms susceptible to UNASYN should not require the addition of another antibiotic.

CONTRAINDICATIONS

The use of UNASYN is contraindicated in individuals with a history of hypersensitivity reactions to any of the penicillins.

WARNINGS

SERIOUS AND OCCASIONALLY FATAL HYPERSENSITIVITY (ANAPHYLACTIC) REACTIONS HAVE BEEN REPORTED IN PATIENTS ON PENICILLIN THERAPY. THESE REACTIONS ARE MORE APT TO OCCUR IN INDIVIDUALS WITH A HISTORY OF PENICILLIN HYPERSENSITIVITY AND/OR HYPERSENSITIVITY REACTIONS TO MULTIPLE ALLERGENS. THERE HAVE BEEN INDIVIDUALS WITH A HISTORY OF PENICILLIN HYPERSENSITIVITY WHO HAVE EXPERIENCED SEVERE REACTIONS WHEN TREATED WITH CEPHALOSPORINS. BEFORE THERAPY WITH A PENICILLIN, CAREFUL INQUIRY SHOULD BE MADE CONCERNING PREVIOUS HYPERSENSITIVITY REACTIONS TO PENICILLINS, CEPHALOSPORINS, AND OTHER ALLERGENS. IF AN ALLERGIC REACTION OCCURS, UNASYN SHOULD BE DISCONTINUED AND THE APPROPRIATE THERAPY INSTITUTED.

SERIOUS ANAPHYLACTOID REACTIONS REQUIRE IMMEDIATE EMERGENCY TREATMENT WITH EPINEPHRINE, OXYGEN, INTRAVENOUS STEROIDS, AND AIRWAY MANAGEMENT, INCLUDING INTUBATION, SHOULD ALSO BE ADMINISTERED AS INDICATED.

PRECAUTIONS

General: A high percentage of patients with mononucleosis who receive ampicillin develop a skin rash. Thus, ampicillin class antibiotics should not be administered to patients with mononucleosis. In patients treated with UNASYN the possibility of superinfections with mycotic or bacterial pathogens should be kept in mind during therapy. If superinfections occur (usually involving *Pseudomonas* or *Candida*), the drug should be discontinued and/or appropriate therapy instituted.

Drug Interactions: Probenecid decreases the renal tubular secretion of ampicillin and sulbactam. Concurrent use of probenecid with UNASYN may result in increased and prolonged blood levels of ampicillin and sulbactam. The concurrent administration of allopurinol and ampicillin increases substantially the incidence of rashes in patients receiving both drugs as compared to patients receiving ampicillin alone. It is not known whether this potentiation of ampicillin rashes is due to allopurinol or the hyperuricemia present in these patients. There are no data with UNASYN and allopurinol administered concurrently. UNASYN and aminoglycosides should not be reconstituted together due to the *in vitro* inactivation of aminoglycosides by the ampicillin component of UNASYN.

Drug/Laboratory Test Interactions: Administration of UNASYN will result in high urine concentrations of ampicillin. High urine concentrations of ampicillin may result in false positive reactions when testing for the presence of glucose in urine using Clinitest™, Benedict's Solution or Fehling's Solution. It is recommended that glucose tests based on enzymatic glucose oxidase reactions (such as Clinistix™ or Testape™) be used. Following administration of ampicillin to pregnant women, a transient decrease in plasma concentration of total conjugated estriol, estriol glucuronide, conjugated estrone, and estradiol has been noted. This effect may also occur with UNASYN.

Carcinogenesis, Mutagenesis, Impairment of Fertility: Long-term studies in animals have not been performed to evaluate carcinogenic or mutagenic potential.

Pregnancy

Pregnancy Category B: Reproduction studies have been performed in mice, rats, and rabbits at doses up to ten (10) times the human dose and have revealed no evidence of impaired fertility or harm to the fetus due to UNASYN. There are, however, no adequate and well controlled studies in pregnant women. Because animal reproduction studies are not always predictive of human response, this drug should be used during pregnancy only if clearly needed. (See—Drug/Laboratory Test Interactions.)

Labor and Delivery: Studies in guinea pigs have shown that intravenous administration of ampicillin decreased the uterine tone, frequency of contractions, height of contractions, and duration of contractions. However, it is not known whether the use of UNASYN in humans during labor or delivery has immediate or delayed adverse effects on the fetus, prolongs the duration of labor, or increases the likelihood that forceps delivery or other obstetrical intervention or resuscitation of the newborn will be necessary.

Nursing Mothers: Low concentrations of ampicillin and sulbactam are excreted in the milk; therefore, caution should be exercised when UNASYN is administered to a nursing woman.

Pediatric Use: The efficacy and safety of UNASYN have not been established in infants and children under the age of 12.

ADVERSE REACTIONS

UNASYN is generally well tolerated. The following adverse reactions have been reported.

Local Adverse Reactions

Pain at IM injection site—16% Pain at IV injection site—3%
Thrombophlebitis—3%

Systemic Adverse Reactions

The most frequently reported adverse reactions were diarrhea in 3% of the patients and rash in less than 2% of the patients.

Additional systemic reactions reported in less than 1% of the patients were: itching, nausea, vomiting, candidiasis, fatigue, malaise, headache, chest pain, flatulence, abdominal distension, glossitis, urine retention, dysuria, edema, facial swelling, erythema, chills, tightness in throat, substernal pain, epistaxis and mucosal bleeding.

Lower antibiotic costs without lowering your standards. UNASYN costs at least 40% less per day than clindamycin/gentamicin or cefoxitin.[11] Yet UNASYN is at least as effective in a variety of mixed infections.*[3,12-19]

And in some studies versus combination therapy, patients treated with UNASYN spent fewer days in the hospital.[3,16,17]

So, look to UNASYN for highly effective, highly affordable therapy in mixed infections* every day.

"We need gold-standard results that don't cost a fortune."

BECAUSE CONFIDENCE COUNTS...

In the successful treatment of venous disorders, both up-to-the-minute knowledge and the proper tools play significant roles. Also important is the confidence of knowing you're getting support for both from an industry leader. In the compression therapy industry, that means Camp International. Decades of experience have established Camp in the leadership position. That's because you can count on Camp for a full line of compression therapy products to meet most any need:

- **Camp graduated compression stockings** for therapy in cases of primary varicose veins, postphlebitic syndrome and other venous diseases. Readily available in sizes, styles and compressions to fit 90-95% of all patients.
- **LymphaPress® and Hemaflo 2® compression systems** for lymphedema, venous ulcers and deep vein thrombosis.

- **Seminars and Educational Programs** that support your efforts, including CME-accredited seminars, hospital in-service sessions, and extensive dealer training programs to ensure prompt and accurate filling of your prescriptions.
- **Patient Education Materials,** including a wide range of brochures to help you educate patients and encourage maximum compliance with your treatment program.

I WANT TO KNOW MORE ABOUT THE CAMP GRADUATED COMPRESSION STOCKING.

☐ Have a Camp representative call on me

☐ Send complete information ☐ Send a demonstration sample

MEDICAL STOCKINGS
CAMP®

CAMP MEDICAL STOCKINGS: Setting A New Standard Of Excellence.

Patient compliance is the key to successful compression therapy. Camp Medical Stockings provide a range of benefits to ensure patient compliance and effective, lasting treatment of venous disorders, so that your patients can continue to lead normal, active lives:

- **Physiologically correct pressures** from 20-30mm Hg. to 50-60mm Hg. and **extensive sizes and styles**—This permits accurate prescriptions for 90-95% of your patients.
- **Double-wrapped yarn**—Yarns in Camp Medical Stockings are double wrapped for improved comfort and greater durability. Unwrapped or single-wrapped yarn can produce bare spots when stockings are stretched. These bare spots cause patient discomfort as well as fraying of the material.
- **Low modulus, high elongation yarn**—Use of this yarn allows for greater elasticity with no loss of compression. This yarn, coupled with a knitting process which allows for more stitches per inch of fabric, results in easier application and greater patient comfort.
- **Electronic knitting process**—The knitting of each Camp Medical Stocking is electronically monitored to ensure consistency in both compression values and fit.
- **Cosmetically acceptable**—The aesthetically pleasing, neutral colors of Camp Medical Stockings encourage maximum patient compliance.

GENERAL SURGEON

Seeking a BC/BE general surgeon to join an established three man surgical practice located in the Washington Metropolitan area. Excellent salary and benefits. Partnership opportunities available.

Send curriculum vitae to:

P.O. Box 1095
Greenbelt, MD. 20770

CHAIRMAN DEPARTMENT OF SURGERY

A 271 bed community hospital, located in a residential area of South Philadelphia, has a position available for Chairman of the Department of Surgery. We are a preferred affiliate of one of the major teaching institutions in Philadelphia with residents on rotation in Medicine, Surgery, Obstetrics and Gynecology, ENT and Emergency Medicine.

Located in close proximity to the Sports Complex, Philadelphia International Airport, major bridges and the interstate highway system, the Emergency Room is active in treating trauma and admits 60% of those patients to the Hospital.

Six newly constructed operating rooms provide the physicians with adequate space to perform in excess of 6000 surgical procedures per year. A very active Obstetrics Service delivers over 1700 babies per year.

Interested individuals should forward their CV to:

Frank A. Bove, M.D.
Chairman, Search Committee
Methodist Hospital
2301 South Broad Street
Philadelphia, Pennsylvania

What will you tell her about screening mammography?

Many of your patients will hear about screening mammography through a program launched by the American Cancer Society and the American College of Radiology, and they may come to you with questions. What will you tell them?

We hope you'll encourage them to have a screening mammogram, because that, along with your regular breast examinations and their monthly self examinations, offers the best chance of early detection of breast cancer, a disease which will strike one woman in 10.

If you have questions about breast cancer detection for asymptomatic women, please contact us.

Evaluation of Prostacyclin Production by Human Gallbladder

Donald L. Kaminski, MD; Y. G. Deshpande, MS; Scott Westfall, MD; David Herbold, MD

• The prostanoids have been demonstrated to be involved in gallbladder physiology and disease. In previous reports, prostaglandin E (PGE) compounds were found to be increased in inflamed human gallbladders. Prostaglandin synthetase inhibition decreased PGE formation by human gallbladders; however, the relief of symptoms of cholecystitis did not correlate well with the decrease in PGE formation. This suggested that other prostanoids may be involved in cholecystitis. The purpose of this study was to evaluate the production of the proinflammatory arachidonic acid metabolite prostacyclin by gallbladders from patients with calculous cholecystitis. The formation of PGE and 6-ketoprostaglandin $F_{1\alpha}$ (6-keto-$PGF_{1\alpha}$), the stable metabolite of prostacyclin, in normal human gallbladder mucosal cells and muscle tissue was compared with that produced by diseased mucosal cells and muscle tissue. Normal human gallbladders produced small amounts of 6-keto-$PGF_{1\alpha}$, and no differences in formation rates were evident when muscle tissue was compared with mucosal cells. Diseased gallbladders produced significantly greater amounts of 6-keto-$PGF_{1\alpha}$ than did normal gallbladders, and diseased gallbladder muscle produced approximately four times greater amounts of 6-keto-$PGF_{1\alpha}$ than did diseased gallbladder mucosa. Prostacyclin formation is increased in diseased human gallbladders and may be an important mediator of the inflammatory changes of cholecystitis.

(*Arch Surg* 1989;124:277-280)

Arachidonic acid metabolites are recognized as having an important role in inflammatory processes involving the liver[1] and biliary tract[2] and possibly as being involved in gallstone formation.[3] Prostaglandin synthetase inhibitors have been found to be effective in the treatment of the pain of cholecystitis.[4]

In a previous report, the cyclo-oxygenase inhibitor ibuprofen relieved the pain of gallbladder disease. However, the inhibition of prostaglandin E (PGE) production did not correlate well with relief of pain.[4] This suggested that other prostanoids may be involved in the production of the pain and the inflammatory response associated with cholecystitis. Prostacyclin is an arachidonic acid derivative present in most tissues that inhibits platelet aggregation and is a vasodilator substance. Prostacyclin has considerable proinflammatory effects and, in most systems, is more potent than are the PGE compounds.[5]

The purpose of the present study was to evaluate prostacyclin production by human gallbladder tissue, by measuring the stable metabolite of prostacyclin, 6-keto-prostaglandin ($PGF_{1\alpha}$).[6] We intended to compare 6-keto-$PGF_{1\alpha}$ levels in normal gallbladders with those found in diseased gallbladders with various degrees of inflammation.

SUBJECTS AND METHODS

Twenty-four patients underwent cholecystectomy, with measurement of the amount of PGE and 6-keto-$PGF_{1\alpha}$ formed by gallbladder tissue. Four male and two female patients (54 ± 7 years of age [mean ± SD]) had no gallbladder symptoms or known biliary tract disease and underwent incidental cholecystectomy at the time of hepatic resection or insertion of hepatic artery catheters for regional chemotherapy to treat hepatic colorectal cancer metastases. These gallbladders were used to determine normal values.

Eighteen patients, six men and 12 women (47 ± 5 years of age), had acute or chronic calculous cholecystitis and underwent cholecystectomy for gallbladder disease.

Informed consent to perform the experiment was obtained from the patients, and the study was approved by the Institutional Review Board for Human Experimentation, St Louis University Medical Center. None of the patients had used cyclo-oxygenase or lipo-oxygenase inhibitors, including aspirin, before the operation.

Immediately following removal of the gallbladder, it was opened and the fluid contained collected on ice for measurement of its protein content by the method of Bradford.[7] The gallbladder was then washed in iced saline solution and the mucosal surface inspected by a pathologist. If no mucosal tumors were present, two 1 × 2-cm full-thickness strips were excised. One was placed in 4% formaldehyde solution for histologic evaluation. The other strip was placed in ice-cold 50-mmol/L TRIS hydrochloride buffer, pH 7.0, containing 2.5 mmol/L of edetic acid, homogenized and used for measurement of β-glucuronidase activity.[8] The activity of the enzyme is reported as units per milligram of homogenate protein. The remainder of the gallbladder was placed in iced tissue culture medium. Utilizing techniques described previously[4] the gallbladders underwent immediate separation of mucosal cells from muscle tissue. An ice-cold solution of 0.25 mol/L of sodium chloride and 2.5 mmol/L of edetic acid, pH 7.5, was injected into the submucosa with a 25-gauge needle. The gallbladder was soaked in the same ice-cold medium for five minutes and shaken to release

Medium	729 ± 157	1990 ± 484†
Homogenate	508 ± 144	2440 ± 637†

*6-Keto-$PGF_{1\alpha}$ indicates 6-ketoprostaglandin $F_{1\alpha}$; PGE, prostaglandin E. These values are expressed in picograms per milligram of protein. Each tissue culture medium value is the mean ± SEM of the number of values indicated obtained from the mean of three hourly samples. Each homogenate value is the mean ± SEM of the number of values indicated.

†Diseased gallbladder value is significantly different from normal gallbladder value.

the mucosal cells. The gallbladders were again soaked for five minutes in fresh edetic acid medium and shaken. The solutions were pooled and the mucosal cells collected by centrifugation for five minutes at 2500 g. The pellet was washed twice in iced Krebs-Ringer phosphate solution, pH 7.5, to remove white and red blood cells[4] and the sample pooled by centrifugation at 200 g for one minute. The separation techniques yielded 200 to 500 mg of mucosal cells.

The remaining gallbladder mucosal surface was scraped by a glass slide and the gallbladder wall washed with Krebs-Ringer phosphate solution, pH 7.5. A 200- to 300-mg piece was minced with scissors and knife to the smallest pieces possible and the resulting tissue washed twice with Krebs-Ringer phosphate solution and the samples were pooled by centrifugation at 200 g for one minute.

Mucosal cells and muscle tissue cultures were performed as described previously in 15 mL of medium.[4] Mucosal cells and muscle tissue were viable as estimated by trypan blue exclusion before and at the end of three hours of culture (>80% viable). Hourly 1-mL samples of culture medium were withdrawn and replaced with fresh medium. At the end of three hours, the medium containing mucosal cells and muscle tissue was removed from the incubator and centrifuged for five minutes at 2500 g. One milliliter of medium was removed, and the mucosal cells and muscle tissue were processed for determination of PGE and 6-keto-$PGF_{1\alpha}$ concentrations by homogenization in 1 mL of ice-cold 50-mmol/L TRIS hydrochloride buffer, pH 7.0, containing edetic acid. The amount of protein present in the mucosal cell or muscle tissue pellet was determined by the method of Bradford.[7]

Prostaglandins in the tissue culture media and homogenates were extracted, purified, and measured by radioimmunoassay according to the method reported by Powell,[9] as modified by Stephenson et al[10] and Suzuki et al.[11] To determine recovery, 2000 to 3000 cpm of tritiated PGE_2 or 6-keto-$PGF_{1\alpha}$ was added. One milliliter of tissue culture medium or tissue homogenate was adjusted to a pH of 3.0 with 0.1N hydrochloric acid, and then 4 mL of 1:1 mixture of ethylacetate-cyclohexane was added. The mixtures were vortexed and then centrifuged at 1500 g for ten minutes. The organic layer was separated and the extraction was repeated again. The organic layers were dried under nitrogen at 4°C.

The dried samples were mixed with 2.25 mL of water and 0.75 mL of alcohol, then vortexed, and 0.14 mL of 1N hydrochloric acid was added. The samples were applied to octadecylsilane packed (Sep-Pack C_{18}) columns that had been previously washed with 20 mL of alcohol, 20 mL of high-performance liquid chromatography water, and 20 mL of 15% alcohol to remove polar lipids and then with 20 mL of petroleum ether. The columns were eluted with 10 mL of methyl formate, which removed the prostaglandins. The methyl formate fractions were collected, evaporated to dryness under nitrogen, and then dissolved in 1 mL of 0.05 mol/L of phosphate buffer, pH 6.8, containing 0.9% sodium chloride, 0.01% edetic acid, 0.3% bovine gamma globulin, 0.005% (octy)phenoxy polyethoxyethanol (Triton-X-100), and 0.05% sodium azide. Recovery was determined by counting 100 μL. Prostaglandin E level was measured by radioimmunoassay as described previously.[4]

For radioimmunoassay of 6-keto-$PGF_{1\alpha}$, the tracer iodine 125–labeled 6-keto-$PGF_{1\alpha}$ was diluted with 50 mmol/L of phosphate buffer, pH 6.8, to a specific activity of 10 000 cpm/dL. The antibody was similarly diluted to provide binding of 50% to 60%. The assay was carried out in 12 × 7.5-mm siliconized glass tubes with standard 6-keto-$PGF_{1\alpha}$ from 2.0 to 500 pg/100 μL per tube. To all the tubes, including the samples, 100 μL of diluted ^{125}I–6-keto-$PGF_{1\alpha}$ was added. This was followed by adding 100 μL of diluted antibody except for the total count and nonspecific binding tubes. The tubes were vortexed and incubated overnight at 2°C. Following incubation, the tubes were placed in an ice-water bath. One milliliter of polyethylene glycol (16%; molecular weight, 6000) as a precipitating agent was added to all the tubes except the total count tubes. The tubes were vortexed and then centrifuged at 1500 g for 30 minutes. The supernatant was decanted, and the pellet was counted in a gamma counter.

The amount of cross-reaction between the antibody for 6-keto-$PGF_{1\alpha}$ was 2.6% with $PGF_{2\alpha}$, 1.9% with PGE, 1.4% with thromboxane B_2, and less than 1% with all other prostanoids. Recovery of 6-keto-$PGF_{1\alpha}$ ranged from 60% to 65%. The intra-assay coefficient of variation was 2%, and the interassay coefficient of variation was 5%.

Each section of gallbladder wall was evaluated histologically after hematoxylin-eosin staining. The histologic evaluation of the amount of inflammation present was performed by a pathologist using a scoring system estimating the amount of inflammatory cell infiltrate, edema, tissue necrosis, muscle thickening, and fibrosis, with 0 being none and 3 being severe.[12] The histologic slides were coded to "blind" the pathologist.

Statistical analysis of the difference between mean (±SEM) values was performed by analysis of variance or Student's *t* test. Determination of correlation coefficients by the method of least squares was used to determine the relationship between prostaglandin levels and β-glucuronidase activity. Spearman rank correlation and Wilcoxon rank-sum test were used to evaluate the histologic scores of inflammation and prostaglandin levels. As used throughout the manuscript, significant indicates $P<.05$.

RESULTS

Normal and diseased human gallbladder mucosal cells and muscle tissue released PGE and 6-keto-$PGF_{1\alpha}$ into

tissue culture medium, and cell and tissue homogenates were found to contain both prostanoids. Both 6-keto-$PGF_{1\alpha}$ and PGE were identifiable in all gallbladders evaluated. Muscle tissue produced significantly more 6-keto-$PGF_{1\alpha}$ than did mucosal cells (Table 1). Human gallbladders produced more PGE than 6-keto-$PGF_{1\alpha}$. Mucosal cells and muscle tissue appeared to produce similar amounts of PGE, as evaluated in tissue culture medium and in muscle tissue homogenates (Table 1).

It has been difficult previously to obtain normal gallbladders, and we previously compared gallbladders with minimal inflammation with those with severe inflammation.[4,12] In the present study, access to an adequate-sized sample of normal gallbladders enabled us to compare normal with diseased tissue (Table 2).

We have been attempting to identify an objective, quantitative index of the degree of cholecystitis present. The lysosomal enzyme, β-glucuronidase, is derived from invading inflammatory cells, and the activity of the lysosomal enzyme parallels the severity of the inflammatory response.[13,14]

Both β-glucuronidase activity and the histologic score of inflammation were significantly greater in diseased gallbladders than in normal gallbladders (Table 2). A significant correlation existed ($r=.637$, $P<.001$) between the histologic score of inflammation and β-glucuronidase activity.

Protein concentration in gallbladder fluid has been implicated in gallstone formation and has been demonstrated to increase in experimental cholecystitis.[15,16] Comparison of the protein concentration of the luminal contents of normal gallbladders with that present in diseased gallbladders revealed no significant differences (Table 2).

Normal gallbladder mucosal cells and muscle tissue produced relatively small and similar amounts of 6-keto-$PGF_{1\alpha}$ in culture media and homogenates. Significantly greater 6-keto-$PGF_{1\alpha}$ was produced by diseased gallbladders than normal gallbladders (Table 2).

Greater amounts of PGE than 6-keto-$PGF_{1\alpha}$ were produced by normal and diseased gallbladders. Diseased gallbladders produced greater amounts of PGE than did control gallbladders for all factors evaluated except when mucosal cells in tissue culture media were evaluated (Table 2).

Attempts to evaluate the degree of correlation between β-glucuronidase activity levels or the histologic score of inflammation with 6-keto-$PGF_{1\alpha}$ levels revealed no significant correlations. When normal values were included in the analysis and when they were not, such significant correlations were able to be demonstrated when comparing β-glucuronidase and histologic inflammation with PGE production. As has been found previously,[4,12] when histologic score was compared with mucosal cell homogenate PGE values, the correlation coefficient was $r=.541$ ($P<.05$). Prostaglandin E production appeared to be more positively correlated with inflammation than was 6-keto-$PGF_{1\alpha}$.

COMMENT

Prostacyclin is formed by human gallbladder muscle and mucosa. In the canine intestinal tract, prostacyclin is formed by both muscularis and mucosal tissues.[17] As is true in human gallbladder muscle tissue (Table 2), the intestinal tract and stomach muscle tissue produce more prostacyclin than is formed by mucosal cells.[17]

Others have demonstrated prostacyclin production by guinea pig[18] and prairie dog[8] gallbladders, unspiked by arachidonic acid, with 6-keto-$PGF_{1\alpha}$ levels quantitatively similar to those produced by human gallbladders. Prostaglandin E compounds may play a role in gallbladder muscle contraction[19] and mucosal water transport,[20] as well as gallbladder inflammation.[2] We are unaware of any studies having been performed to ascertain if prostacyclin alters any physiologic gallbladder function. The prostacyclin in gallbladder muscle and mucosa may be formed by blood vessels[17] and may function in the vasodilation associated with inflammation.

In an experimental model of gallstone formation, produced by feeding prairie dogs a high-cholesterol diet, prostaglandins have been shown to be involved in gallstone formation. Prostaglandin formation is stimulated by increased bile cholesterol.[21] Prostaglandins stimulate secretion of mucin, which acts as a nidus for gallstone formation.[8] Mucin secretion and experimental gallstone formation are inhibited by prostaglandin synthetase inhibitors.[22,23] In experimental cholelithiasis, mucin secretion appears to be regulated by endogenous prostacyclin levels.[22] The data in the present report demonstrate significantly greater prostacyclin levels produced by gallbladders from patients with gallstones than from patients with normal gallbladders. The increased prostanoid levels may be contributing to stone formation as well as subsequent inflammation.

We have previously demonstrated that systemic infusion of prostacyclin increases hepatic bile flow, producing a bicarbonate-rich choleresis mediated by cyclic adenosine monophosphate.[24] The response produced was not due to regional blood flow changes.[24] It will be important for improved understanding of the results in the present study to determine if prostacyclin has any effect on gallbladder contraction or absorption.

Our previous studies of prostaglandin formation by diseased human gallbladder was inhibited by the relative difficulty in obtaining normal gallbladders for comparison. Organ donors are not a suitable source for normal gallbladders for prostanoid evaluation because of the steroid therapy used for immunosuppression. Currently, a variety of operative procedures are performed that require incidental cholecystectomy, such as regional hepatic chemotherapy and hepatic resection, providing access to disease-free gallbladders. As these gallbladders require operative removal, with the associated tissue trauma[25] and hypoxia,[26] the prostanoid levels present may not be absolutely normal. The ability in this study to compare similarly procured normal and diseased gallbladders enhanced our understanding of the changes in arachidonic acid metabolism that was occurring.

Measurement of the lysosomal enzyme β-glucuronidase as a marker of white blood cell invasion correlated well with the severity of inflammation present, as evaluated histologically. It is likely that measurement of other lysosomal enzymes[27] would produce similar information, and perhaps lysosomal enzymes even more specific for gallbladder inflammation will be identified. β-Glucuronidase measurements clearly allowed the separation of normal from diseased gallbladders.

In acute experimental models of cholecystitis, diseased gallbladders secrete a protein-rich fluid into the lumen of the gallbladder.[16] This process is believed to be mediated by prostaglandins, as it is inhibited by prostaglandin synthetase inhibition.[28] In the present study, the protein content of fluid obtained from the gallbladders at the time of cholecystectomy in normal gallbladders was not significantly different from that found in diseased gallbladders. All of the diseased gallbladders contained gallstones, and perhaps intraluminal fluid protein content may only be important in acalculous cholecystitis.[16]

Though previous studies have demonstrated that PGE production by human gallbladder muscle tissue and mucosal cells increased with increasing severity of the inflammatory process,[4,12] the present study indicates that gallbladders from patients with calculous cholecystitis have increased PGE production compared with normal gallbladders (Table 2). The increased PGE levels may contribute to the inflammatory response,[4,12] pain,[19] and gallbladder fluid accumulation[20] and indeed may be involved in gallstone formation related to prostaglandin-mediated production of mucin, which acts as a nidus for nucleation of cholesterol crystals.[3] Prostanoid formation appears to be an important factor in human gallbladder disease.

This study was supported by grant DK 27695 from the US Public Health Service.

Hospital-Acquired Candidemia: The Attributable Mortality and Excess Length of Stay

Sergio B. Wey, MD; Motomi Mori, MS; Michael A. Pfaller, MD;
Robert F. Woolson, PhD; Richard P. Wenzel, MD, MSc

Between 1977 and 1984, estimates of hospital-acquired bloodstream infections caused by *Candida* species increased in the United States from 0.5 to 1.5 per 10 000 admissions (National Nosocomial Infection Study data). We examined crude and attributable mortality rates and excess length of stay in 88 closely matched pairs of cases and controls with illnesses occurring between July 1983 and December 1986. The crude mortality rates for cases and controls were 57% and 19%, respectively; thus the attributable mortality rate was 38% with a 95% confidence interval of 26% to 49%. The risk ratio was 2.94 with a 95% confidence interval of 1.95 to 4.43. The median length of stay was 48 days for all cases and 40 days for all controls. An analysis of the length of stay for the 34 matched pairs that survived showed a median of 70 days for cases and 40 days for controls. *Candida* bloodstream infections represented 10% of all nosocomial bloodstream infections in the period studied at our University Hospital; they are associated with a significant medical and economic burden well above that expected of the underlying diseases alone (*Arch Intern Med* 1988;148:2642-2645).

The Efficacy of Oral Antimicrobials in Reducing Aerobic and Anaerobic Colonic Mucosal Flora

Jonathan I. Groner, MD; Charles E. Edmiston, Jr, PhD; Candace J. Krepel; Gordon L. Telford, MD; Robert E. Condon, MD, MS

• We investigated the impact of intestinal antisepsis on the colonic mucosa-associated flora. Four groups of dogs were studied: group A received no bowel preparation, group B received a three-day clear-liquid diet, group C underwent mechanical cleansing of the bowel, and group D had mechanical cleansing followed by oral neomycin and erythromycin. Mucosal biopsy specimens were obtained for bacteriologic and scanning electron microscopic (SEM) studies. No significant difference in recovery of mucosal bacteria was observed between groups A and B. A significant decrease in recovery of aerobes was observed in group C, and a significant decrease in both aerobes and anaerobes was observed in group D compared with group A; Enterobacteriaceae and *Bacteroides* were either eliminated or greatly reduced. The SEM analysis of group D revealed a marked decrease in mucosa-associated microflora compared with groups B and C. Oral neomycin-erythromycin produced a significant quantitative reduction in the colonic mucosa-associated bacterial population, including the potentially pathogenic *Escherichia coli* and *Bacteroides fragilis* group isolates. These mucosa-associated bacteria are a likely source of contamination of the abdominal cavity and wound at the time of colon surgery.

(*Arch Surg* 1989;124:281-284)

The use of prophylactic antimicrobials in patients undergoing elective colon surgery has been extensively studied, clinically and experimentally, for over 30 years.[1] In current clinical practice, prophylaxis is administered by parenteral, oral, or combination regimens.[2] The strategy behind parenteral preoperative antimicrobial administration is to assure that adequate microbicidal levels of the drug are present in the wound at the time of initial tissue contamination.[3] In comparison, the strategy behind the administration of the oral combination of erythromycin and neomycin is to reduce the microbial flora in the colonic lumen. This combination has been demonstrated to reduce the incidence of septic complications in a blinded, randomized, controlled clinical trial.[4] Erythromycin, a macrolide antibiotic, exhibits activity against anaerobes as well as gram-positive aerobic (including facultatively aerobic) microorganisms. Bactericidal levels of erythromycin can be found in the serum and stool of patients after oral doses of this drug.[5] Neomycin, an aminoglycoside, is active against aerobic and facultative coliforms; it is poorly absorbed and acts within the bowel lumen.

Intraluminal sampling has demonstrated that oral administration of neomycin and erythromycin reduces bacterial counts in the residual colonic contents.[6] However, the impact of oral prophylaxis on the bacteriology of the colonic mucosal surface has not been previously examined. Previous studies in man have demonstrated that the mucosa-associated colonic bacteria are a discrete subpopulation of the luminal flora exhibiting strong adherence to the brush-border surface. This adherent microflora includes *Bacteroides*, fusobacteria, peptostreptococci, and some members of the Enterobacteriaceae that are resistant to removal by mechanical cleansing or mucosal washes.[7]

Subinhibitory levels of antimicrobials have been documented to alter microbial adhesion in vitro.[8] The administration of oral antibiotics may be effective in reducing the concentration of mucosa-associated bacteria, theoretically leading to a reduction in wound contamination and infection risk. The purpose of the present investigation was to determine whether mechanical bowel preparation, followed by oral administration of neomycin and erythromycin, is effective in reducing the numbers of aerobic (facultative) and anaerobic (obligate) mucosa-associated colonic bacteria.

MATERIALS AND METHODS

Animals

This study was approved by the animal experimentation institutional review board. Twenty-eight dogs were randomly assigned to four different groups. In group A (n = 6), six dogs received food

*Counts reflect number of biopsy specimens harboring each isolate. Total number of biopsy specimens per study group: A, 18; B, 21; C, 24; and D, 21.

†Recovered Enterobacteriaceae included *Escherichia coli, Klebsiella, Enterobacter, Citrobacter, Proteus,* and *Morganella; E coli* was the most predominant isolate in groups A, B, and C.

‡Aerobic miscellaneous isolates included corynebacteria, facultative lactobacilli, and staphylococci.

§Anaerobic miscellaneous isolates included bifidobacteria, *Megasphaera,* propionibacteria, and *Veillonella.*

and water ad libitum without any bowel preparation. Group B (n = 7) dogs were placed on a 72-hour clear-liquid diet. The third group of dogs, group C (n = 8), was given a 72-hour clear-liquid diet, and then 280 g of magnesium citrate orally, followed by a tap water enema. Group D dogs (n = 7) underwent a similar mechanical bowel preparation and, in addition, received oral neomycin sulfate (500 mg) and erythromycin base (500 mg) at noon, 1, and 6 PM on the day before study.

In groups A, B, and D, mucosal biopsy specimens were obtained at laparotomy. In group C, the specimens were obtained by colonoscopy (Olympus Model CF-1B). To obtain a mucosal biopsy sample free of contamination by flora foreign to the immediate sample site, a sealed polyethylene catheter (Clay Adams PE 160) containing a gas-sterilized biopsy instrument was introduced through the biopsy channel of the colonoscope. At the biopsy site, the instrument was pushed through a paraffin seal at the catheter tip, and the mucosa underwent biopsy. The biopsy instrument was drawn back into the catheter and the biopsy probe and catheter were removed together from the colonoscope. The process was repeated for each biopsy in the proximal, middle, and distal colon using a fresh catheter-sheath instrument.

Dogs undergoing laparotomy (groups A, B, and D) had a ventral midline incision performed using general endotracheal anesthesia after skin preparation with povidone-iodine scrub solution and sterile draping. The colon from just distal to the cecum to just proximal to the rectum was isolated and divided. Using separate sterile scissors for each biopsy, a sample of mucosa was obtained from proximal, middle, and distal colon sites. All samples were immediately placed in gassed-out vials and transported to the laboratory.

Bacteriology

After wet-weight determination (tissue weight range, 2.1 to 12.9 mg), the biopsy specimens were placed inside an anaerobic chamber where all tissue homogenization, serial dilution with buffered gelatin diluent, and plating was carried out. The following media for aerobic and anaerobic isolation were inoculated using a 0.01-mL calibrated loop: trypticase-soy blood agar, colistin–nalidixic acid blood agar, *Enterococcus*-selective agar, Sabouraud dextrose agar, Centers for Disease Control (CDC formulation) anaerobic blood agar, kanamycin-vancomycin blood agar, egg yolk agar, phenylethyl alcohol agar, *Lactobacillus*-selective agar, modified *Fusobacterium* medium, and *Bifidobacterium* medium. Aerobic media were incubated at 36.5°C and examined at 24 and 48 hours. All aerobic bacterial isolates were characterized by standard methods.[9]

Anaerobic bacteria initially were characterized on the basis of macroscopic and microscopic criteria. The isolates were tested for oxygen tolerance in an atmosphere supplemented with 5% carbon dioxide. Strict anaerobes were inoculated into prereduced, anaerobically sterilized, carbohydrate media. Volatile and nonvolatile metabolic by-products were analyzed by gas-liquid chromatography. Biochemical evaluations were carried out using standard techniques.[10] Microbial quantitation was expressed as $\log_{10}$ colony-forming units (CFUs) per milligram (wet weight) of mucosal tissue.

Scanning Electron Microscopy

Specimens for scanning electron microscopy (SEM) were immediately prefixed for eight hours in 2% glutaraldehyde, buffered with 0.15 mmol/L of sodium cacodylate (pH, 7.4). After several buffered washes, the specimens were postfixed in 1% osmium tetroxide. Following serial dehydration, the specimens were critical point dried from liquid CO_2 and then coated with gold-palladium in an evaporator. The processed specimens were viewed in an SEM at 20 kV with a spot size of 8 nm.

Statistical Analysis

The quantitative data were analyzed by the paired *t* test to compare biopsy sites within a given treatment group. Comparisons of bacterial recovery for different treatment groups at a given site were performed using analysis of variance and the nonpaired *t* test.

RESULTS

Eighty-four colonic mucosal biopsy specimens were obtained from 28 dogs. The mean biopsy weight was 9.2 mg in group A (no preparation), 8.7 mg in group B (clear-liquid diet), 7.1 mg in group C (mechanical preparation), and 10.8 mg in group D (antibiotic preparation group). No significant differences in quantitative aerobic or anaerobic recovery were observed between biopsy sites within a study group (Table 1) or between groups A and B. There was a significant difference in recovery of aerobes between groups B and C ($P<.05$) but no difference in obligate anaerobe recovery. Both aerobes and anaerobes were significantly decreased in group D dogs ($P<.01$) compared with controls (group A).

A broad and complex microbial flora was recovered in

A, Scanning electron micrograph of colonic mucosal surface in group B dog (clear-liquid diet regimen) demonstrating intact mucin sheath in which rods and cocci are embedded (×2400). B, Colonic mucosal surface in group C dog (mechanical preparation) demonstrates some mucus debris along with heterogeneous mucosa-associated bacteria (×3000). C, Mucosal surface in group D dog (given oral antibiotics) showing no microorganisms present in proximal colonic biopsy specimen (×4000). D, Arrow points to single coccilike organism residing on brush-border surface in another group D biopsy specimen (×3200).

group A (Table 2). *Bacteroides*, Enterobacteriaceae, fusobacteria, peptostreptococci, and clostridia were the predominant mucosa-associated flora in the control (group A) dogs as well as in groups B and C. In group D, no Enterobacteriaceae or clostridia were recovered from any of the 21 biopsy samples. *Bacteroides*, *Fusobacterium*, and peptostreptococci were recovered from less than one quarter of the group D specimens.

In group B, SEM revealed a mucosal surface with a dense mucin layer. Numerous rods and cocci were observed residing within the gel-like matrix (Figure, part A). Mechanical preparation removed much of the mucin from the mucosal surface, revealing a luxurious mucosa-associated microflora (Figure, part B). Treatment with oral neomycin and erythromycin removed most of the mucosa-associated microorganisms (Figure, parts C and D).

COMMENT

Postoperative septic complications following elective colon surgery are usually the result of contamination by endogenous microorganisms.[11] The predominant bacteria in the large bowel are the anaerobic gram-negative, nonspore-forming bacilli. These organisms are present in the colon lumen at concentrations of 10^9 to 10^{11} organisms per gram of stool.[4] Aerobic (facultative) gram-negative bacilli represent only 1% to 10% of the total endogenous colonic flora; however Enterobacteriaceae are a significant cause of morbidity and mortality following elective abdominal surgery.[12,13] A variety of other aerobes and anaerobes, including clostridia and enterococci, also can be cultured from the stool, while fungi in large numbers are rarely cultured from the stool of young, healthy individuals.[14,15] Bartlett et al[16] and Edmondson and Rissing[17] have shown that the predominant isolates recovered from infected sites following elective colon operations were *Bacteroides fragilis* and *Escherichia coli*.

Previous reports have documented the failure of mechanical preparation alone to reduce significantly the intraluminal microbial population of the colon.[6,12] Furthermore, the use of mechanical preparation by itself has been shown to be associated with a higher incidence of septic complications.[4,11] Using tissue biopsy, we have demonstrated that vigorous mechanical preparation appears to eliminate mucin-bound bacteria but does not significantly reduce mucosa-associated aerobes or anaerobes compared with a nonmechanically (liquid diet) prepared group of dogs.

In dogs receiving both mechanical preparation and oral antimicrobials, there was a significant reduction in both aerobes and anaerobes compared with the control group (aerobic-facultative reduction, 5.2 to 6.2 $\log_{10}$ CFUs/mg of tissue vs group A; anaerobic reduction, 6.7 to 7.2 $\log_{10}$ CFUs/mg of tissue vs group A). The concentration of

residual mucosa-associated bacteria in group D following oral administration of neomycin-erythromycin (Table 1) was below the microbial density often present in a wound following a clean-contaminated procedure, and below the concentration (10^5) at which wound infection may occur. Furthermore, qualitative analysis demonstrated that Enterobacteriaceae and *Bacteroides* were either eliminated or significantly decreased in the oral antimicrobial–treated group (Table 2). The predominant organisms isolated after oral prophylaxis were of low inherent virulence (eubacteria, lactobacilli, and facultative streptococci) and, therefore, unlikely to cause postoperative septic complications.

In conclusion, a regimen of mechanical bowel cleansing followed by oral administration of neomycin and erythromycin significantly decreases the mucosa-associated facultative and obligate microbial populations of the colon and, in so doing, eliminates or reduces those bacteria often responsible for postoperative intra-abdominal and wound infections. Without the addition of oral antimicrobials, such as neomycin and erythromycin, the mucosa-associated bacteria remain unchanged and are a potential source of contamination of the wound and abdominal cavity at the time of operation.

We wish to thank Marcey Jaskulski for her technical assistance in preparing the manuscript.

ARCHIVES OF INTERNAL MEDICINE

Factors Predictive of Acute Renal Failure in Rhabdomyolysis

Michael M. Ward, MD, MPH

In a historical cohort study, acute renal failure developed in 16.5% of 157 patients with rhabdomyolysis over a two-year study period. Underlying clinical, laboratory, and causative factors associated with the development of acute renal failure were examined. Factors predictive of renal failure in this setting, determined by multiple logistic regression analysis, included the degree of serum creatine kinase, serum potassium, and serum phosphorus level elevation; the degree of depression of serum albumin level; and the presence of dehydration at presentation or sepsis as the underlying cause. The predictive model that was developed correctly classified 93% of subjects and was statistically validated (*Arch Intern Med* 1988;148:1553-1557).

Emergency Abdominal Operations in the Patient With Acquired Immunodeficiency Syndrome

Joshua H. Burack, MD; Marc S. Mandel, MD; Lawrence S. Bizer, MD

• We have reviewed the medical records of ten patients with acquired immunodeficiency syndrome who required emergency celiotomy in a three-year period. These operations are characterized by a high morbidity and mortality. Careful attention to the support of these immunosuppressed, malnourished patients if emergency operation is necessary may improve the poor results reported herein.

(*Arch Surg* 1989;124:285-286)

Acquired immunodeficiency syndrome (AIDS) has become a recognized disease entity to most physicians. The protean infectious and malignant complications of AIDS and its causative agent(s) have been identified. The diagnosis and treatment of intra-abdominal pathologic conditions in patients with AIDS represent a formidable challenge to surgeons. Furthermore, as would be expected, major surgical procedures result in high morbidity and mortality in a group of patients with marked immunosuppression abetted by frequent protein calorie malnutrition. The following report documents our experience with emergency celiotomy in patients with AIDS.

PATIENTS AND METHODS

A medical record review at Montefiore Medical Center, Bronx, NY, and its two affiliated municipal hospitals over a three-year period (June 1984 to July 1987) revealed ten patients with AIDS who underwent emergency celiotomy for acute intra-abdominal disease. All ten patients met Centers for Disease Control criteria for the diagnosis of AIDS.[1] All patients were followed up until their deaths or the time of this writing. Particular attention was paid to the preoperative opportunistic infections the patients had acquired as well as the likely cause of human immunodeficiency virus transmission and the nutritional status of the patients. Presenting signs and symptoms of intra-abdominal pathologic conditions, preoperative and postoperative diagnosis, surgical procedures performed, and pathologic examination of the tissue removed at operation were all examined. In addition, close attention was paid to postoperative complications and mortality.

RESULTS

Nine of the ten patients were men. The average age was 36.7 years (range, 27 to 44). Eight (80%) of the ten patients were intravenous drug abusers, one was a homosexual, and the tenth patient was a heterosexual with prostitute contacts. All of the patients appeared malnourished, and, although nutritional profiles had not been done, the mean serum albumin level was 26 g/L (range, 18 to 35 g/L), with 70% having a level below 30 g/L. The diagnosis of AIDS had been established an average of 5.5 months before operation. Five patients had *Pneumocystis carinii* pneumonia and one each had disseminated histoplasmosis, cryptococcal meningitis, and Kaposi's sarcoma. The remaining two patients had documented *Candida* esophagitis. Six of the infections were active at the time abdominal symptoms began.

In every case, the patient initially complained of abdominal pain. The average rectal temperature was 38.2°C, with a range from 36.7°C to 38.9°C. Two patients were afebrile (temperature, <37.8°C). Seven of the ten patients had involuntary guarding and rebound tenderness, whereas in three patients there was only mild abdominal tenderness. Interestingly, the average white blood cell count was only 6.8×10^9/L, with a range from 2.1 to 15×10^9/L. Nine of the ten patients had a white blood cell count of less than 10×10^9/L, but 50% of patients had 10% or more band forms seen on differential count.

In five patients, clinical presentation alone mandated an operation. In the other five patients, the decision to operate was based on additional radiographic findings: a radionuclide biliary scan showing acute cholecystitis (two), pneumoperitoneum on upright chest roentgenography (two), and progressive small-bowel obstruction on abdominal roentgenograms (one).

In 40% of the patients, the preoperative and operative diagnosis differed, but all abdominal explorations were indicated (Table). Postoperative complications were frequent. They included three wound infections, three wound dehiscences, one intestinal anastomotic leak, one ostomy revision required because of bowel necrosis, two postoperative small-bowel obstructions (both requiring reoperation), and four patients with ventilator-dependent respiratory failure postoperatively.

Seven of the ten patients died postoperatively; six never left the hospital, and the seventh patient was readmitted soon after hospital discharge for an anastomotic leak and abdominal wound dehiscence and died five weeks later. Three patients survived their postoperative course; two died five and 24 months postoperatively of AIDS-related diseases, and one patient is still alive six months postoperatively.

COMMENT

In 1984, Potter et al[2] described five patients with AIDS with abdominal pain, four of whom underwent celiotomy. Two of the four patients died within one month of operation. Subsequent reports in the English-language literature

*AIDS indicates acquired immunodeficiency syndrome.
†Greater than two months.

document a total of at least 11 cases of emergency celiotomy in patients with AIDS. Six died within one month of operation. An unusual spectrum of pathologic conditions was found in these cases. Cytomegalovirus was responsible for four colon perforations, one small-bowel perforation, and a megacolon in one patient. In addition, cases of disseminated intra-abdominal cryptococcosis, atypical Kaposi's sarcoma, and lymphoma are described.[3-6] The majority of our patients had intra-abdominal surgical problems commonly seen in patients without AIDS, but we did treat one patient with a cecal perforation due to cytomegalovirus, a small-bowel stricture due to *Strongyloides* infestation, and an ileocecal intussusception due to atypical mycobacteria infection (Table).

Fever and leukocytosis are variably present in these individuals, as is typical of immunosuppressed patients. Hubbard et al[7] reported a series of seven renal transplant patients who developed peritonitis. Only two were febrile, and another two patients had leukocytosis.

The atypical histories in these patients with previous or ongoing infections in other organ systems and immunosuppression all contribute to the difficulty of establishing a diagnosis requiring operative intervention. In addition, patients with AIDS are poor surgical risks. Typically, the postoperative course is punctuated by complications directly related to the surgical procedure and a high incidence of ventilatory failure. The patients commonly spend a protracted postoperative period in the intensive care unit, only to succumb to sepsis and multiple organ failure (Table).

In the United Kingdom, the patient with AIDS has an average life expectancy of 13.5 months from the time of diagnosis.[8] In our small series of patients, the average survival from the time of a diagnosis of AIDS was only ten months, suggesting that emergency abdominal operations (and the disease that necessitated operation) hasten the patient's demise. Others have questioned whether emergency surgical procedures should be performed in these patients, particularly if they appear near death before the development of a surgical catastrophe.[9] Our limited data cannot answer this question.

It is also important to remember that this series of patients represents the high morbidity and mortality of emergency celiotomy in the patient with AIDS, and the results do not necessarily pertain to elective surgical procedures in patients with AIDS. Furthermore, the results do not necessarily pertain to elective or emergency surgical procedures in patients who are human immunodeficiency virus antibody positive or who have AIDS-related complex (ARC). There is, however, evidence that elective anorectal surgical procedures in patients with AIDS or ARC are fraught with a high incidence of complications and poor wound healing.[10] Thus, one would expect that subsequent reports in the medical literature will document great difficulties in successfully operating on patients with AIDS or ARC electively and for surgical emergencies.[4]

Errors in Estimating Energy Expenditure in Critically Ill Surgical Patients

Vincente Cortes, MD, Loren D. Nelson, MD

• Thirty-one critically ill surgical patients were receiving central parenteral nutrition. All were intubated, and 29 were receiving mechanical ventilatory support. Nutritional and metabolic data were recorded at the time of indirect calorimetry. Measured energy expenditure (MEE) was compared with predictions of basal energy expenditure (BEE) and *calculated energy expenditure,* defined as the product of BEE and a stress factor estimated by the nutrition support service to account for severity of illness and activity. The MEE was significantly greater than the BEE and significantly less than the calculated energy expenditure. The estimated stress factor was significantly greater than the actual MEE/BEE ratio, and the correlation between these values was poor. Clinical assessment may overestimate energy expenditure in critically ill patients because of the apparent degree of illness used to determine the stress factor. Bedside indirect calorimetry may be useful to assess more accurately energy expenditure and optimize nutritional support.

(*Arch Surg* 1989;124:287-290)

Central parenteral nutrition (CPN) regimens are formulated to optimize total energy intake and fractional requirements of protein, carbohydrate, and fat. Total energy requirement is frequently calculated using the Harris-Benedict equations to estimate basal energy expenditure (BEE).[1] The clinical estimate of a patient's actual energy expenditure (calculated energy expenditure [CEE]) is the product of BEE times a stress factor to estimate the fraction by which actual energy expenditure exceeds the basal value.[2-4] Energy expenditure can also be measured by direct or indirect calorimetry.

Increased interest in nutritional support of hospitalized patients brought about the rebirth of indirect calorimetry.[5-8] Technical considerations have limited the application in intubated patients receiving supplemental oxygen and mechanical ventilatory support. The development of an adequate interface between ventilator and patient and the refinement of precise measuring instruments have made indirect calorimetry a reality in these cases.[9,10]

We used indirect calorimetry to assess clinical estimates of energy expenditure as a reflection of actual energy expenditure in a group of critically ill surgical patients.

SUBJECTS AND METHODS

Patient Population

The records of 100 consecutive patients studied by indirect calorimetry in the Surgical Intensive Care Unit at Jackson Memorial Hospital, Miami, were reviewed. Indications for metabolic measurements included carbon dioxide retention, difficulty in ventilator weaning, shock, sepsis, acute respiratory failure, and monitoring of CPN. Thirty-one of these patients who were receiving CPN at the time of measurement were selected for this study. Twenty-five patients had undergone major surgery, and six had sustained thoracoabdominal trauma. All patients were intubated and were receiving supplemental ventilatory support sufficient to produce a comfortable breathing pattern and respiratory rate.

All the patients had been evaluated by the Nutritional Support Service, and recommendations for specific CPN regimens, including total energy requirement and percentages of each major component (protein, carbohydrate, and lipid), had been made. The consultation forms entered in the patient's chart by the Nutritional Support Service were reviewed, and information regarding height, weight, BEE calculated according to the Harris-Benedict equations, stress factor, CEE, and nutritional recommendations were obtained for each patient. Nitrogen balance was calculated as protein intake divided by 6.25 minus the 24-hour urinary urea nitrogen excretion plus 3 g for insensible losses.

Other information recorded included level of mechanical ventilatory support, arterial blood gas results, actual nutritional components being infused, and the estimated activity level of the patient at the time of measurements. All patients were intubated, and all but two were receiving mechanical ventilatory support (fractional inspired oxygen concentration, 0.21; intermittent mandatory ventilation rate, two or more breaths per minute; positive end-expiratory pressure, ≥ 5 cm H_2O).

Indirect Calorimetry

Oxygen consumption and carbon dioxide production were measured using a portable bedside indirect calorimeter (Metabolic Gas Monitor—MGM/Two, Utah Medical Products, Midvale). The device measures differences in the concentration of oxygen and carbon dioxide between inspired gas and expired gas, as well as the minute expired volume. It has previously been subjected to bench testing[9] and clinical validation in similar critically ill patients using the same interface between the device and the ventilatory

§Significantly less than SF ($P<.025$).

circuit.[10] The measurements were made over periods ranging from 30 minutes to two hours. When steady-state values were obtained, measured energy expenditure (MEE), oxygen consumption, carbon dioxide production, and respiratory quotient were recorded.

Statistical Analysis

Measurements of various parameters are expressed as mean ± SD. The Student's *t* test for paired data was used for determinations of differences between variables. Correlation between values was assessed by linear regression analysis. Probability values less than .05 were considered statistically significant.

RESULTS

The group included 15 male and 16 female patients, with a mean age of 56 ± 20.6 years (range, 15 to 82 years) and a mean body surface area of 1.78 ± 0.41 m^2 (range, 1.4 to 2.3 m^2). The mean mechanical ventilatory support levels were as follows: fractional inspired oxygen concentration, 0.40 ± 0.11 (range, 0.21 to 0.47); intermittent mandatory ventilation rate, 3.2 + 2.1 breaths per minute (range, zero to eight breaths per minute); and positive end-expiratory pressure, 5.5 ± 2.2 cm H_2O (range, 5 to 15 cm H_2O). Arterial

*MEE indicates measured energy expenditure; BEE, basal energy expenditure; CEE, calculated energy expenditure; UUN, urinary urea nitrogen excretion; AV, arteriovenous.

blood gas results and metabolic measurements are shown in Table 1.

The patient's diagnosis, MEE and estimated energy expenditure, stress factor, ratio of MEE to BEE, and 24-hour urinary urea nitrogen excretion are listed in Table 2. Nitrogen balance varied widely in these patients; mean nitrogen balance was a positive 1.0 ± 6.9 g/d.

Measured energy expenditure (7730 ± 2050 kJ/d) was significantly greater than BEE (5910 ± 1310 kJ/d) ($P<.001$), and there was a significant correlation between the two values ($r=.67$, $P<.001$) (Fig 1). Measured energy expenditure (7670 ± 2040 kJ/d) was significantly less than CEE (8590 ± 1700 kJ/d) ($P<.01$), and there was a significant correlation between the two values ($r=.56$, $P<.005$, Fig 2).

The estimated stress factor (1.47 ± 0.13) was significantly greater than the actual ratio between MEE and BEE (1.32 ± 0.36) ($P<.025$), and the correlation between those two values was poor ($r=-.13$, $P>.05$, Fig 3).

Neither the estimated stress factor nor the ratio of MEE to BEE correlated with the 24-hour urinary urea nitrogen value ($r=-.01$, $P>.05$).

COMMENT

Frequent use of nutritional support has increased the desire to appraise energy requirements of critically ill patients. Calculation of BEE and measurement of actual energy expenditure have been used clinically.[11,12] Basal energy expenditure is the energy requirement of a normal individual at rest in the fasting state, ten to 18 hours after a meal, and physically relaxed in a neutral-thermal environment and is also called *basal metabolic rate*. The clinical estimate of a patient's actual energy expenditure (CEE) is the product of BEE times a stress factor to estimate the fraction by which actual energy expenditure exceeds that basal value.[2-4]

One of the most common methods to estimate BEE uses multiple regression equations developed by Harris and Benedict in 1919. These calorimetric studies, performed on awake, resting, normal subjects, indicated that sex, height, weight, and age are the primary determinants of BEE.[1]

Since BEE estimates "basal" energy expenditure, it is multiplied by a stress factor to estimate the energy requirements for a specific individual and circumstance.[3] The stress factor accounts for the increased expenditure related to specific dynamic action of the nutrients, activity, illness, fever, trauma, and surgery. Cerra[13] suggested a simple system for the estimation of the stress: low, 1.3; moderate, 1.5; severe, 2.0.

Indirect calorimetry has been reintroduced for the bedside measurement of energy expenditure, but technical difficulties have limited application in critically ill patients receiving supplemental oxygen and mechanical ventilatory support.[7,8,12] These same patients are often highly stressed, and the correction factors used to calculate energy expenditure vary widely. Overfeeding of carbohydrate substrate may result in hyperglycemia, hyperosmolar states, osmotic diuresis, fatty infiltration of the liver, increased carbon dioxide production, and worsening of respiratory failure.[14-22]

With the use of indirect calorimetry, we detected errors in the estimation of energy expenditure in patients in the surgical intensive care unit. While BEE, CEE, and MEE correlated statistically, MEE was significantly greater than BEE, calculated using the Harris-Benedict equations, and significantly less than the CEE, calculated using an estimated stress factor. The stress factor used for the CEE

Fig 1.—Correlation between measured and basal energy expenditure ($r=.67$, $P<.001$) ($y=620+0.43x$).

Fig 2.—Correlation between measured and calculated energy expenditure ($r=.56$, $P<.005$) ($y=1199+0.46x$).

Fig 3.—Correlation between ratio of measured to basal energy expenditure (MEE/BEE) and estimated stress factor ($r=-0.13$, $P<.05$) ($y=1.72-0.27x$).

did not correlate with the actual stress factor calculated as the MEE/BEE ratio or with other indicators of catabolism, such as 24-hour urinary urea nitrogen excretion.[3]

Calculation of energy expenditure involves several sources of error. Height and weight may not be known in bedridden, critically ill patients. Measured weight may not reflect usual weight because of prehospitalization losses, water volume changes related to primary illness or associated complications, and intravenous fluid resuscitation.[23] Height may not be known, and measurements of length may not correlate with height.[24]

The Harris-Benedict equations, while validated by other workers to within ±5% from 1936 to 1956, have more recently been shown to yield results varying between −14.1% to +19.1% when compared with measurements made by indirect calorimetry.[25]

It appears that clinical estimation of stress is responsible for the observed divergence between CEE and MEE. Clinical impressions may overestimate actual stress because support technology makes the patient appear to be sicker than he is. Our results support this contention and point to the estimation of the stress factor as the primary source of error.

While it is possible that this overestimate of metabolic needs is specific to our institution, it is our impression that it is more widespread. Physician awareness of this problem will be important to avoid overfeeding of critically ill patients. More frequent use of indirect calorimetry in the critical care setting may facilitate the administration of nutritional support by providing objective measurements of actual energy expenditure and substrate use.

Hans Anderson, RRT, assisted in the development of the interface techniques and validation of the metabolic monitor. Cliff Reistler and the Nutritional Support Service at Jackson Memorial Hospital performed the metabolic assessments.

ARCHIVES OF PATHOLOGY & LABORATORY MEDICINE

Inflammatory Aneurysm of the Aorta, Aortitis, and Coronary Arteritis

Stephen D. Cohle, MD, J. T. Lie, MD

Inflammatory aneurysm of the aorta is not merely a variant of atherosclerosis, but more probably it is a manifestation of a peculiar systemic disease related to idiopathic retroperitoneal and mediastinal fibrosis. Rarely, aortitis and coronary arteritis may coexist with the inflammatory aneurysm; one of each of such unusual cases are described. Because inflammatory aneurysms of the aorta tend to occur in elderly persons, aortitis and coronary arteritis, when present, cannot be distinguished from the concomitant age-related atherosclerosis without a careful histologic examination (*Arch Pathol Lab Med* 1988;112:1121-1125).

Hemostasis of Solid Viscus Trauma by Intraparenchymal Injection of Fibrin Glue

Carl J. Hauser, MD

• Fibrin glue (FG) is an effective hemostatic agent applied topically to the spleen. In this study, FG was found to be an effective hemostatic agent when applied topically in standardized wounds of the canine liver, spleen, and pancreas. It was markedly more effective, however, when injected intraparenchymally. In a case of severe blunt trauma in a patient with acute alcoholic hepatitis, intraparenchymal FG was lifesaving. Fibrin glue is a useful adjunct in the management of trauma to all the abdominal solid viscera. Intraparenchymal injection is the preferred mode of FG application.

(*Arch Surg* 1989;124:291-293)

Hemorrhage from injured solid organs may be difficult to control. Solid viscera hold sutures poorly, injured vessels may be deep within the organ, and bleeding from the parenchyma itself may be life-threatening, especially when coagulopathy occurs. On occasion, the surgeon must perform undesirable resective procedures,[1,2] pack the abdomen,[3-5] or accept incomplete hemostasis at the time of closure. Such situations might be avoided if more effective methods of solid organ hemostasis were available.

Fibrin glue (FG) is formed by mixing a source of concentrated fibrinogen with thrombin and is hemostatic in mild to moderate splenic trauma.[6-8] When splenic trauma is severe, however, FG is less effective.[7] In these cases, FG tends to be washed off by the stream of blood prior to polymerization or to be lifted off of the treated surface soon afterward by bleeding beneath the coagulum. Thus, a method of application appropriate to the parenchymal injuries seen in hepatic and severe splenic trauma has not been described. This communication reports my experience using intraparenchymal FG (IPFG) to avoid such displacement of the FG coagulum.

METHODS

Experimental Injuries

Twenty-four hepatic injuries were produced in 12 mongrel dogs. General anesthesia was induced by ketamine hydrochloride and pentobarbital sodium (Nembutal). The liver was exposed at laparotomy. Injuries were produced in a random sequence. In each dog, a slash incision 8 cm in length and 1.5 cm deep was made in the right lobe of the liver, and a stab incision was made in the left lobe by plunging a No. 10 scalpel into the liver to a depth of 5 cm. All wounds bled freely (>50 mL/min). Twelve wounds were fashioned in the spleens of six of the above dogs. One slash wound 4 cm long and 1 cm deep and one stab wound formed by plunging a No. 10 scalpel blade to a depth of 2.5 cm were created in each animal's spleen. In six dogs, the distal 2.5 cm of the descending limb of the pancreas was dissected free from the duodenal mesentery and amputated.

Administration of FG

Fibrin glue was prepared from a kit containing concentrated fibrinogen and bovine thrombin. The two substrates are mixed as the glue is delivered through a needle. By using concentrated thrombin solution, polymerization was effected within 10 to 15 s. Wounded areas were first compressed to obtain hemostasis until the glue had polymerized. Fibrin glue was applied topically (TFG) by allowing it to flow freely onto the cut surface until a polymerized seal had formed. Injection into the wound (IPFG) was performed using a sharp 18-gauge needle advanced 1 cm into the parenchyma via the capsular wound and then moved back and forth during injection as for the creation of a field block with a local anesthetic. Injections were done such that FG oozed out of tissue and polymerized on the surface of the wound. The temporary compression of the organ was then released.

Half of the wounds of each type were treated, respectively, with TFG and IPFG as the initial hemostatic modality. In all cases, each treatment used 4 to 6 mL of glue. As an internal control to test for the effects of the wound compression on hemostasis in these wounds, four hepatic stab and four hepatic slash wounds were each initially compressed for a period of one minute and then released. In all cases, free bleeding recurred immediately, and these wounds were subsequently treated with TFG or IPFG. In subsequent dogs, this test was omitted. After release of compression, the wounds were inspected for one minute and then were judged hemostatic (no assessable bleeding) or nonhemostatic (showing continued free bleeding or hematoma formation). Nonhemostatic wounds were treated with a second application of TFG or IPFG. If two applications of FG failed, that wound was "crossed over" to the other method of FG administration.

Statistical Analysis

Dogs were reoperated on and killed at one week to three months to assess any possible complications of therapy and to determine the fate of the wound repairs. The abilities of TFG, IPFG, and

Accepted for publication June 20, 1988.

Table 1.—Hemostasis in Hepatic Slash Wounds*

	Control Achieved		Control Not Achieved
	1 Application	2 Applications	
Tamponade	0	0	4
TFG	3	3	0
IPFG	6	0	0

*TFG indicates topical fibrin glue; IPFG, intraparenchymal fibrin glue. Both TFG and IPFG were significantly more effective hemostatic modalities than simple tamponade of the wound ($\chi^2=14.6$, $P<.001$ for both modes of administration). Intraparenchymal FG was successful after the first application significantly more frequently than was TFG ($\chi^2=5.45$, $P<.02$).

Table 2.—Hemostasis in Hepatic Stab Wounds*

	Control Achieved		Control Not Achieved
	1 Application	2 Applications	
Tamponade	0	0	4
TFG	0	3	3
IPFG	6	0	0

*TFG indicates topical fibrin glue; IPFG, intraparenchymal fibrin glue. Both TFG and IPFG were significantly more effective hemostatic modalities than simple tamponade of the wound ($\chi^2=5.73$ [$P<.02$] and $\chi^2=14.6$ [$P<.001$], respectively). One application of IPFG was significantly more likely to effect hemostasis in a deep hepatic stab wound than either one or two applications of TFG ($\chi^2=16.33$ [$P<.001$] and $\chi^2=7.11$ [$P<.01$], respectively).

compression alone to produce hemostasis were compared by χ^2 analysis, with statistical significance assumed at the $P<.05$ level.

RESULTS

Of the six hepatic slash wounds treated with TFG, all showed marked initial diminution of bleeding, but in three of six the bleeding recurred. A second TFG application achieved complete hemostasis in all six. Of the six slash wounds treated primarily with IPFG, all achieved complete hemostasis on the first application (Table 1).

Six hepatic stab wounds were treated initially with TFG. Three achieved hemostasis, in each case after two applications. Two stab wounds continued to bleed, and one formed a hematoma despite two TFG applications. These three wounds were treated with IPFG and were hemostatic after one IPFG application. Of six hepatic stab wounds treated primarily with IPFG, all became hemostatic after the first application (Table 2).

The six superficial lacerations of the spleen were all treated successfully with either one (four of six) or two (two of six) applications of TFG. Intraparenchymal FG was not tested in these injuries. Of the deep splenic lacerations, three of six were successfully treated with a single application of TFG. The other three injuries bled despite two applications of TFG, but were then controlled by a single application of IPFG.

Topical FG did not achieve hemostasis in any pancreatic injuries. Hemorrhage from arteries in the pancreatic substance easily lifted the FG seal off of the pancreas. Intraparenchymal FG was used subsequently and achieved somewhat better success. Hemostasis was achieved in all cases; however, two applications of IPFG were required in four of the six injuries, and in three of these four cases hematomas formed beneath the FG seal.

Except for one dog who died intraoperatively of an anesthetic complication, all dogs recovered in a routine fashion. No dog developed clinical peritonitis, jaundice, or sepsis. At reexploration, no dog was found to have bile leakage, pancreatitis, ascites, or hemoperitoneum. No hepatic parenchymal hematomas were noted. In pathologic specimens obtained during the first postoperative week, IPFG administration sites were noted to form a continuous gel that traversed the wounds, filling the parenchyma as well as the wound itself. Intraparenchymal FG caused a slight space-occupying effect, with bulging of the specimen's cut surface at the IPFG injection site. Topical FG and IPFG sites disappeared over the course of three to four weeks, leaving a fibrous capsular scar.

REPORT OF A CASE

A 32-year-old man was found lying in the street and was brought to Hollywood Presbyterian Trauma Center, Los Angeles. He was hypotensive, agitated, and jaundiced. A thoracoabdominal tire-track mark was noted. The hematocrit reading was 0.23; the blood alcohol level was 428 mg/dL. After resuscitation, the patient was taken to the operating room. Laparotomy revealed an enormously enlarged, fatty liver. The posterior lateral left hepatic lobe was severely fractured, as was the spleen. Acute pancreatitis with saponification was noted. Rapid splenectomy was performed. Attempts at suture of the friable liver exacerbated the bleeding. Hepatic artery ligation and lobar resection were thought contraindicated by hepatitis and saponification in the porta hepatis. The liver was packed, and the abdomen was closed. Over the next 48 hours, the patient required 6 U of packed red blood cells. He was treated for cardiac and pulmonary contusions, acute respiratory distress syndrome, delirium tremens, Wernicke's encephalopathy, and coagulopathy. On the third hospital day, the patient developed polymicrobial sepsis. After Food and Drug Administration approval of possible use of FG on humanitarian grounds, the patient underwent another laparotomy. The left upper quadrant was exposed by division of the costal margin. Packs were gently dissected off the liver using a water pick. Nonetheless, life-threatening hemorrhage recurred. The liver was compressed medial to the injuries, and FG was injected into the liver parenchyma around the fracture sites until it ran into the fractures and filled them up. Compression was maintained for two minutes and then released. Hemostasis was complete. A subcapsular hematoma due to retraction of the liver was noted. The hematoma was unroofed, revealing diffuse bleeding but no fracture. This was controlled by TFG. Multiple soft silicone sump drains were placed, and the abdomen was closed. The drains were nonproductive and were removed at one week. The patient was discharged one month after his injury. Computed tomographic scan performed three weeks after injury showed continued fatty replacement but no residual injuries.

COMMENT

The efficacy of TFG in human splenic salvage has been established in European studies,[6,7] but to my knowledge the use of FG in hepatic trauma has not been reported. Topical FG seems to be quite adequate to obtain hemostasis in the mildly to moderately injured spleen. In the deeply lacerated spleen and in the injured liver, however, IPFG seems to be more effective. In these experimental injuries, immediate hemostasis was achieved more frequently by IPFG than TFG, in both the slash ($\chi^2=5.45$, $P<.02$) and the stab ($\chi^2=16.33$, $P<.001$) wounds. This seems to be related to three factors. First, the fibrin is anchored to the wound by extension of the polymer into the adjoining parenchyma. Second, causing the FG to "percolate" through the parenchyma seals the parenchymal sites, which may persist in bleeding after discrete bleeding sites have been controlled. Third, injection of FG directly into the parenchyma seems to cause a "mass effect," with tamponade of bleeding from surrounding tissues.

In bleeding pancreatic injuries, FG was less effective.

Topical FG was easily lifted off of the organ capsule by the bleeding. Also, IPFG did not spread through pancreatic parenchyma as readily as through liver or spleen. Thus, arterial bleeding from the pancreas was only controlled by repeated application of IPFG. Venous bleeding, however, and leakage of pancreatic juices were controlled by IPFG.

The case study demonstrates that use of FG can effect hemostasis where bleeding might not be controllable by conventional methods. The lack of bile leakage seen in this patient, as well as in the canine model, suggests that FG prevents leakage of bile from hepatic injuries. The absence of residual computed tomographic evidence of injury at three weeks suggests that the human liver heals rapidly in the presence of FG, with total reabsorption at three to four weeks, as reported in canine spleen.[8]

Fibrin glue is an effective hemostatic agent in solid organ trauma. It should not be expected to control bleeding from major vessels, but it is extremely effective in the control of parenchymal bleeding persisting after major vascular sources have been controlled. The degree of effectiveness varies, depending on the organ and injury in question and on the mode of administration. This study suggests that IPFG is preferred in deep injuries, especially injuries of the liver. Compression of the parenchyma to be injected until the FG polymerizes is useful to maximize local adherence, as well as to eliminate the theoretical danger of embolism to the lungs.

When FG is produced from pooled plasma, its use carries a high risk of hepatitis transmission and thus Food and Drug Administration approval has been limited to individual cases of compassionate need. However, as manufacture of FG from individual donors or synthesized fibrinogen becomes practical,[9] FG will become an important therapeutic modality in solid organ hemorrhage.

Sinusitis in the Nasotracheally Intubated Patient

Barry E. Linden, MD; Eugenio A. Aguilar, MD; Steven J. Allen, MD

Maxillary sinusitis as a complication of nasotracheal intubation has long been recognized as difficult to diagnose and equally difficult to treat. To better define this problem from a diagnostic and therapeutic standpoint, we studied patients admitted to the surgical intensive care unit at the University of Texas Health Science Center at Houston-Hermann Hospital over a six-month period. During this time, we identified 19 cases of maxillary sinusitis. Diagnostic criteria included fever, leukocytosis, purulent rhinorrhea, and maxillary sinus opacification or air fluid level noted on sinus roentgenograms. Patients who met these criteria underwent maxillary sinus aspiration. Sixteen patients were receiving antibiotic therapy when sinusitis was diagnosed. All patients had their endotracheal tubes replaced orally, had diseased maxillary antra lavaged, and underwent appropriate antibiotic therapy guided by culture and sensitivity studies. Four of 19 patients required more than one sinus lavage, but all patients had their sinus disease resolve. These data suggest an aggressive approach to diagnosing sinusitis in the nasotracheally intubated patient is needed. A maxillary sinus aspiration and lavage should be an integral part of the diagnosis and treatment of these patients (*Arch Otolaryngol Head Neck Surg* 1988;114:860-861).

Neutron Therapy for Nonresectable Radioresistant Tumors

Lionel Cohen, MD, Frank R. Hendrickson, MD

• Locally advanced, nonresectable, radioresistant tumors can often be ablated by external irradiation using high-energy fast neutron beams. Long-term local control has been achieved in a wide range of malignant tumors, notably sarcomas of bone and soft tissue and adenocarcinomas in various sites. Complete response and long-term remission, with local control rates between 50% and 70%, have been reported in a number of very large osteogenic sarcomas, soft-tissue sarcomas (particularly neurogenic tumors), melanomas, and adenocarcinomas of the alimentary tract. Malignant salivary gland tumors and carcinoma of the prostate appear to be the most responsive to neutrons, with a high frequency (70% to 90%) of successful remission and significantly improved survival even in advanced stages of disease. The biological mechanisms underlying radioresistance of tumor cells and the rationale for using heavily ionizing particles are described. Neutrons are shown to be a valuable adjunct in managing nonresectable malignant tumors that resist conventional therapy.

(*Arch Surg* 1989;124:294-300)

Surgery, radiotherapy, and chemotherapy are the only modalities, used singly or in combination, that can provide long-term local control of nonmetastatic cancer. In suitably responsive tumors (lymphomas or small epidermoid carcinomas, for example), radiotherapy and/or chemotherapy may be the preferred treatment. In most other situations, complete surgical resection, with or without preoperative or postoperative adjuvant therapy, is the only potentially curative option. However, a real dilemma is posed when a nonresectable tumor, which is also resistant to radiotherapy and chemotherapy, is encountered. Under these circumstances it would be reasonable to explore other modalities that are theoretically able to control such tumors.

MATERIALS AND METHODS

Radioresistant Tumors

Commonly encountered radioresistant tumors include melanoma, sarcoma of the bone and soft tissue, adenocarcinoma of the thyroid, respiratory, and alimentary systems, and peripheral nerve tumors (Table 1). In all these tumor types, permanent ablation can be achieved by radiation, but only with exceptionally large doses, often beyond safe normal tissue tolerance limits.

The resistance of these tumors to conventional radiotherapy has been attributed to (1) the presence, in many tissues and tumors, of repair enzymes that confer on the associated tumor cells an unusually high capacity to sustain and recover from radiation injury; (2) the existence in large necrotic tumors of ischemic (hypoxic) zones in which tumor cells are protected from the lethal effects of the oxidizing radicals normally produced by ionizing radiation in well-oxygenated tissues; (3) production of intracellular reducing substances (such as melanin) that can intercept oxidizing radicals before they can react irreversibly with chromosomal DNA; and (4) variation in the response of cells in different phases of the cell cycle, with the result that slow-growing tumors, having a large proportion of noncycling, relatively insensitive cells, can survive doses of radiation that would be lethal in more rapidly cycling tumors.

These mechanisms are known to be responsible for repair and recovery from sparsely ionizing (low–linear energy transfer [LET]) radiations, which include electrons, x-rays, and gamma rays generally used for radiotherapy. By contrast, irradiation with high-LET particles such as neutrons produces irreversible chromosomal disruption (double-strand breaks), which kills or sterilizes cells independently of the cell cycle, biochemical environment, or treatment time. For this reason, tumors that are resistant to conventional radiotherapy are expected to be markedly more responsive to neutron beam therapy.[1] A number of clinical studies have also confirmed this expectation.[2-4]

Previous Clinical Studies

An active "historical" phase in neutron therapy research was pursued from 1970 to 1985 following reports by Catterall[5] in London on the striking results of neutron therapy for locally advanced cancer of the upper aerodigestive tract. During that period, some 9000 patients were treated in 20 centers throughout the world using relatively low-energy (15- to 30-MeV) cyclotrons designed for research in nuclear physics and adapted for clinical use. Although these beams were not well suited for treatment of deep-seated cancers, some impressive results were reported in a variety of nonresectable radioresistant tumors (Table 2). The current phase of this work commenced at Fermilab in Chicago in 1976 with the development of a high-energy (66-MeV) neutron beam suitable for cross-firing, deep-seated tumors in an isocentric mode analogous to a modern linear accelerator. Hospital-based high-energy cyclotrons now exist in several other centers: Houston, Los Angeles, Seattle, Cleveland, and Detroit in the United States and Louvain, Belgium, Liverpool, England, and Cape Town, South Africa, abroad. Results of current studies, using high-

energy equipment, in selected groups of patients with unresectable, radioresistant tumors, will be described below.

RESULTS

With the exception of the gliomas, in which intensive investigation has so far not shown any advantage of neutron therapy over standard treatment, most radioresistant tumors appear to respond well to high-LET radiations.

Head and Neck

In cancer of the head and neck, stage and histological nature are major determinants of the response to irradiation. In general, locally advanced epidermoid carcinomas and most adenocarcinomas were found to be relatively resistant to conventional radiotherapy and significantly more responsive to neutrons (Color Fig 1).[4,5] Although no survival advantage could be demonstrated in epidermoid carcinomas, neutron therapy did yield a high rate of local control in large tumors and a low incidence of bone necrosis with repair of some bones eroded by tumor, which correlates well with their known physical and biological attributes.[4]

Seventy-six patients with locally advanced cancers of the head and neck have been treated with neutrons at Fermilab.[5] Results were analyzed to study the influence of stage, previous management, site of origin, and tumor histological type on local control of the disease. The most significant factor determining the outcome was the histological type. Long-term local control was achieved in 17 (49%) of 35 patients with epidermoid carcinoma and in 28 (72%) of 39 with nonepidermoid neoplasms (adenocarcinoma, cylindroma, mucoepidermoid carcinoma, and salivary-type tumor). The analysis also showed a survival advantage in nonepidermoid tumors treated with neutrons. It was concluded that neutron beam therapy was probably the treatment of choice for nonresectable or recurrent nonepidermoid cancers of the head and neck. Typical response of a large nonepidermoid oropharyngeal tumor is illustrated in Color Fig 2.

Salivary Gland Tumors

Tumors of the major and minor salivary glands, as well as salivary-type tumors in ectopic sites, have proved particularly responsive to neutron beam therapy, which has now become accepted as the treatment of choice in nonresectable salivary tumors.[6] Locally advanced salivary tumors with commencing facial nerve encroachment have been well controlled, often with full restoration of facial nerve function.[7] Color Fig 3 illustrates a typical result of neutron irradiation for nonresectable carcinoma of the parotid gland.

One hundred thirteen patients with recurrent and/or unresectable malignant salivary-type tumors treated with fast neutron therapy at Fermilab were analyzed for local control, sites of failure, and treatment-related morbidity.[6] Local control was achieved in 42 (67%) of 63 with major, and 29 (58%) of 50 patients with minor, salivary gland tumors. In a subset of patients with oropharyngeal and oral cavity salivary-type tumors, 19 (79%) of 24 were controlled. When the tumor was less than 6 cm in diameter, 74% were controlled; with larger lesions the control rate was 30%. Median survival times were three years for patients with major salivary gland tumors and four years for those with minor salivary gland tumors. In the usual dose range, the complication rate was 16%; these were all successfully managed with minimal residual disability. Results are summarized in Table 3. Neutron irradiation of nonresectable thyroid tumors has yielded essentially similar results.[8]

†Prostatic cancer can be ablated with conventional radiotherapy; however, neutrons have been shown to be significantly more effective in this regard.[12]

Sarcoma of Bone and Soft Tissue

Osteosarcoma and chondrosarcoma are traditionally treated by radical or conservative surgery, with or without chemotherapy. When total tumor ablation is achieved, this method yields a high rate of local control, the major cause of failure being distant metastases. When adequate surgery is not feasible, radical radiotherapy may be the only option, but the very high doses required for cure are not well tolerated by the normal tissues, and the consequences are often destructive. In the axial skeleton, where the target volume may impinge on vital organs, it may be impossible to deliver adequate doses for these relatively radioresistant tumors.

The accepted treatment for soft-tissue sarcomas is resection and postoperative irradiation for ablation of residual microscopic disease. However, surgery may not always be feasible when these tumors occur in the neck or trunk and may be undesirable when a nerve sheath is involved. In these nonresectable soft-tissue sarcomas, conventional radiotherapy has been effective in only a small proportion of patients treated, and for this reason a number of trials with neutron beam irradiation have been instituted in various countries. These trials have generally yielded local control rates between 50% and 70% (Table 2). International experience of 286 soft-tissue sarcomas treated with neutrons yielded 144 (50%) with local control. Similarly, of 118 sarcomas of bone so treated, 74 (63%) were controlled.

A total of 51 patients with exceptionally large tumors were treated at Fermilab[10] for sarcoma of bone (25 patients) and soft tissue (26 patients). Chondrosarcoma was particularly responsive, with a 56% (9/16) control rate. Among the soft-tissue tumors, liposarcoma and neurogenic sarcoma were most responsive. The overall five-year survival rate was 40% in the entire series. Response of a typical nonresectable malignant bone tumor (chondrosarcoma of the chest wall) is shown in Color Fig 4. Responses of irradiated soft-tissue sarcomas (neurogenic sarcoma of the neck and fibrosarcoma of the maxillary antrum) are illustrated in Color Fig 5 and Fig 1.

Colorectal and Pancreatic Adenocarcinoma

Unresectable, residual, or recurrent adenocarcinomas of the gastrointestinal tract (stomach, bowel, rectum) are relatively resistant to irradiation. Initial studies suggest that these tumors may respond better to neutron irradiation,[3] but this has not been confirmed in controlled trials. The response of pancreatic cancer to local irradiation with high-energy neutrons has been thoroughly evaluated at Fermilab.[11] Seventy-seven patients with locally advanced, nonresectable, biopsy-proved adenocarcinoma of the pancreas have been treated with bypass surgery followed by intensive neutron beam irradiation of the primary tumor

Fig 2.—Adenocarcinoma of prostate, stage D1. Top, Pretreatment computed tomographic scan showing massive tumor with bladder invasion; bottom, first six-month follow-up showing initial response. Patient remains well at last checkup (May 1987).

site. No improvement in overall survival was observed. As with most treatments for pancreatic cancer, the median survival time was only six months, but symptomatic palliation was achieved in the majority of patients. With "second look" surgery and at autopsy (19 subjects), complete tumor regression, with reactive fibrosis and minimal residual microscopic tumor, was observed in all cases (Color Fig 6). The major cause of death was metastatic dissemination. Neutron irradiation apparently provides effective local control coupled with many deaths due to metastases, suggesting that better forms of systemic chemotherapy, possibly combined with local high-LET irradiation, would be worth exploring.

Prostate

Carcinoma of the prostate has proved to be exceptionally sensitive to neutron irradiation. Typically, even very large stage C and D1 prostatic tumors have regressed completely following treatment (Fig 2). In a recently completed randomized trial comparing conventional photon irradiation with mixed-beam (photon plus neutron) treatment,[12] the latter was shown to yield significantly better results in regard to both local control and survival.

Lung Cancer

A trial of high-LET radiations in the treatment of non–small-cell lung cancer is currently under way. Of 40 patients treated with neutrons[13] and followed up for two or more years, nine (23%) were locally controlled (seven alive without evident disease), four were alive with local residual disease, 24 (60%) had clinically evident metastases, and only three patients have died of local extension without metastases. These results are not greatly different from those with conventional radiotherapy.

Salvage of Radiation Failures

Few therapeutic options are available for a patient whose tumor has recurred within a field previously treated with a full radical dose of radiation. Neutrons have been used to re-treat patients with advanced recurrent tumors of the head and neck both at Hammersmith Hospital (London) and at Fermilab.[14,15] Forty-six patients who had received prior radical radiotherapy with photons were reirradiated with neutrons at Fermilab for locally recurrent disease. Overall, 21 (46%) of the 46 patients had a complete local response. The tumor regressed completely in eight (80%) of ten recurrent salivary tumors, in nine (39%) of 23 recurrent primary squamous cancers, and in four (67%) of six patients with neck node recurrences. Partial regression and/or palliation of symptoms occurred in a further 22 patients (48%). Only three of the 46 patients showed no response. Significant morbidity was seen in ten patients. It was concluded that neutron therapy can be tolerated by previously irradiated tissues and could be an effective treatment for patients with locally recurrent tumors. Though not without risk of severe side effects, neutron beam therapy is particularly recommended for recurrent salivary gland tumors and for recurrent disease in cervical lymph nodes.

Palliation of Radioresistant Metastatic Disease

Neutrons have generally been used for radical treatment of locally advanced but potentially curable tumors without overt metastases. However, because of the rapid response observed in many tumors that are relatively resistant to conventional radiotherapy, it seemed probable that metastases arising from such radioresistant tumors would also be more amenable to neutron therapy. Patients are currently being treated with neutrons for isolated metastases from adenocarcinomas (salivary gland, prostate, lung, kidney, and bowel) and sarcomas of all types. Although no survival statistics are available, palliation has generally been excellent and exceptionally rapid, often within a few days after starting treatment. Another advantage of neutron palliation is the very short course of treatment required. One to three fractions are usually sufficient to provide complete symptomatic relief.

CONCLUSIONS

Though neutron beam therapy is clearly not a panacea for all advanced cancer, there does appear to be a distinct subset of patients who can benefit substantially from this treatment. In particular, adenocarcinomas (all sites of origin) and sarcomas (soft tissue and bone) are usually amenable to neutron irradiation. The superiority of neutrons over conventional irradiation has been demonstrated unequivocally in the case of salivary gland tumors[6,7] and carcinoma of the prostate.[12] Neutrons are probably indicated in most locally advanced, nonresectable tumors that are classified histologically as radioresistant.

Ethical Use of Yellow Pages Listings by Physicians

Steven M. Denenberg, MD, Howard W. Smith, MD, DMD

A recent article in the *New England Journal of Medicine* examined the percentage of physicians listed under specialty headings in a Yellow Pages publication who were board certified. The authors presented findings that many of the physicians listed in the Yellow Pages, particularly under the heading of "Plastic Surgery," were not board certified. The source data employed in that article were obtained and reexamined, and it was found that the assumptions used were inaccurate and the methodology flawed. Almost every physician listed under "Plastic Surgery" in the Yellow Pages is board certified. We discuss the conclusions of the original article and its recommendations for control of Yellow Pages listings. We believe that these recommendations are not in the public's best interests and may be illegal as well (*Arch Otolaryngol Head Neck Surg* 1988;114:1392-1394).

Gallbladder Response to Enteral Lipids in Injured Patients

Ronald C. Merrell, MD; Priscilla Miller-Crotchett, RN; Patricia Lowry, MD

• Severely injured patients are at risk for complications of gallbladder stasis in a spectrum from sludge formation and cystic duct occlusion by inspissation and, subsequently, acalculous cholecystitis. In a double-blind randomized trial, the effect of enteral lipids on the ability of the gallbladder to clear itself was tested. The gallbladder was assessed by ultrasonography for acute contractions, sludge, and dilatation on days 1, 3, and 7 after injury. There were no significant differences between patients who received enteral lipids and controls. Both groups showed modest enlargement of the gallbladder and failure of contraction. In a population at risk for biliary stasis following severe trauma, standard enteral lipids did not elicit, acutely or chronically, an appropriate reflexive evacuation of the gallbladder.

(*Arch Surg* 1989;124:301-302)

Although the cause of acalculous cholecystitis[1,2] is unknown, well-described groups of patients are at exceptional risk for this condition. These include diabetic patients, patients who receive total parenteral nutrition (TPN) for long periods, and critically ill patients in either a surgical or medical intensive care environment. Factors implicated in acalculous cholecystitis include anesthesia,[2] narcotic analgesics, multiple transfusions,[3] sepsis,[4] and hypotension.[5] One common feature among these patients is a diminished response of the contractile elements of the gallbladder either due to a relative insensitivity to cholecystokinin in the case of diabetic patients[6] or due to failure to elicit cholecystokinin release from the duodenum by lipid secretagogues because the patients are not eating.[7] If the gallbladder is not stimulated to contract, there is a tendency to progressive dilatation, the formation of sludge, and inspissation of this sludge in the cystic duct with cystic duct obstruction.[8] This occlusion is permissive for the development of cholecystitis. In this study, a double-blind design was chosen to test the ability of lipids, instilled into the gastrointestinal tract via nasogastric tube, to promote evacuation of the gallbladder. The hypothesis declared that reflexive emptying would avoid dilatation of the gallbladder, with sludging of the gallbladder bile.

Accepted for publication May 24, 1988.

PATIENTS AND METHODS

Injured patients between the ages of 20 and 65 years who required at least a one-day admission to the surgical intensive care unit and who were, in all likelihood, to take nothing by mouth for seven days were considered for inclusion in the study. Patients with a previous cholecystectomy or direct biliary or duodenal trauma were excluded. All patients had a nasogastric tube that was advanced far into the stomach, and they had no gallstones demonstrable by ultrasound. The patients were randomized to receive, in a "blinded" fashion, either 40 mL of safflower oil (Lipomul)[9-11] or water at 8 AM each day into the very distal nasogastric tube. Ultrasound examination was done on the first day before and after receipt of the safflower oil and then repeated on days 3 and 7. Bedside ultrasonography was performed, and the characteristics for notation included gallbladder length and diameter and wall thickness.[12-14] The presence or absence of pericholecystic edema and the presence or absence of sludge were also noted. The trauma characteristics of the patients are listed in Table 1. The majority of patients arrived by air ambulance from the scene of injury. The representative laboratory values of the study population are listed in Table 2. These were severely injured patients who fit the risk description for acalculus cholecystitis.

RESULTS

All patients survived the observation period, and none was excluded for technical or clinical reasons. All patients were studied under the informed consent provisions of the Committee for the Protection of Human Subjects of The University of Texas Medical School at Houston. Consent was obtained from relatives. There were no complications of the safflower oil administration. No patients developed acute cholecystitis during the course of the study. The results of the measurements are displayed in Table 3. The results of safflower oil instillation on acute gallbladder dimensional changes (mean ± SEM) are as follows: longitudinal diameter, 7.1 ± 0.9 vs 7.0 ± 0.9 cm; transverse diameter, 3.2 ± 0.6 vs 2.8 ± 0.6 cm. These dimensions do not reflect any significant contraction of the gallbladder in response to safflower oil instillation. Safflower oil administration to normal subjects in these circumstances leads to a dramatic response in gallbladder dimension, with at least a 50% reduction in the diameters, and is a tactic that is commonly employed for biliary kinetic analysis in this institution and others.[10] Furthermore, the dimensions of the gallbladder throughout the course of observation showed a modest increase in the longitudinal axis that was

Table 1.—Characteristics of Traumatized Patients

Group	n	Patient's Mean(±SEM) Age, y	% Male	% Air Transport
Control	6	40±8	83	67
Lipid fed	6	30±6	83	100

not affected by the daily administration of the enteral fat. One patient in the safflower oil–treated group and two in the saline solution–treated control group developed gallbladder sludge. Both groups of patients showed modest increases in gallbladder wall thickness throughout the course of this study. The mean total bilirubin level was elevated by day 7 in both groups. This seemed to be a population at risk for biliary complications, but no impact of safflower oil on biliary dimensions could be detected.

COMMENT

Acute acalculous cholecystitis represents a serious and potentially fatal complication among massively injured patients. Although the cause of the condition is unknown, there is good reason to implicate biliary sludge that theoretically can occlude the cystic duct and commence the process of infection in an undrained hollow viscus. Other factors implicated in acalculous cholecystitis include anesthetic effects,[2] narcotic analgesics,[2] multiple transfusions,[3] sepsis,[4] and hypotension.[5] Acalculous cholecystitis has been recognized in patients receiving long-term TPN who are unable to eat.[7,15] Patients who receive long-term TPN also develop bilirubinate stones in addition to their problem with acalculous cholecystitis.[16] Recent data have strongly suggested a salutary effect of cholecystokinin in TPN models to flush and drain the gallbladder periodically.[17] This drainage is effective in prairie dogs that receive long-term TPN to avoid the formation of sludge and has even been useful in reducing cholesterol stone formation in cholesterol-fed prairie dogs. Safflower oil, introduced orally, has been a standard for many years to induce contraction of the gallbladder because of the cholecystokinin released in the duodenum in the presence of lipids. This measure was used for many years with oral cholecystography and, more recently, has been useful in studying gallbladder dynamics with ultrasonography. The technique of ultrasonography to detect gallbladder motility problems, sludge, and signs indicative of incipient or established acalculous cholecystitis has become a matter of general agreement. In this double-blind study, ultrasonography certainly demonstrated changes in the gallbladder that declare the population studied as one at risk for acalculous cholecystitis. However, the ultrasonography failed to show proper response of the gallbladder to enteral safflower oil either acutely or chronically. There are two possible conclusions of the results reported here. The first is that as a consequence of bowel edema and motility changes, there is no stimulation or cholecystokinin released by the enteral lipid. The other possibility is that in severe injury, the gallbladder is not especially responsive to circulating cholecystokinin. In either case, enteral lipid is not effective for reflexive evacuation of the gallbladder in injured patients.

Gastric Adenocarcinoma

A Disease in Transition

Blake Cady, MD; Ricardo L. Rossi, MD; Mark L. Silverman, MD; William Piccione, MD; Thomas A. Heck, MD

• Two hundred eleven gastric adenocarcinomas diagnosed from 1967 to 1982 were analyzed. Thirty-four percent had a proximal location, a proportionate increase from previous decades that suggested a distinctive epidemiology. Diffuse histology occurred in 49% of cases overall and in 55% of unresectable cases, which were also increases from previous decades. No deaths followed curative resections, two (4%) of 50 patients with palliative resections died, and three (6%) of 54 patients who underwent exploration without resection died, indicating improved operative management. Superficial gastric cancer constituted 6% of cases; 91% were cured. Seventeen percent of cases were linitis plastica and required total gastrectomy in 77% of resections; only 13% of patients had curative operations; none were cured. Seventy-nine percent of cases were polypoid or ulcerated focal cancers. Of operable focal cancers, 72% were resected; 27 (47%) of 57 patients who underwent resection for cure survived five years, a distinct improvement from previous reports, as was the overall survival of 21%.

(*Arch Surg* 1989;124:303-308)

Until 1975 the incidence and death rate of gastric adenocarcinoma had been falling dramatically, but in 1986 the number of deaths predicted from gastric cancer was the same as in 1976, indicating a plateau in the death rate, while the estimated number of new cases actually rose by 8%, from 22 900 in 1976 to 24 700 in 1986.[1,2] Gastric cancer is the sixth leading cause of death by cancer in men and the ninth leading cause in women,[2] and thus still represents a formidable problem in clinical cancer treatment. A ten-year survey of the pathology and the results of therapy at the Lahey Clinic Foundation, Burlington, Mass, that concluded in 1966, with a ten-year follow-up, was published in 1977.[3] The present report covers the subsequent 15 years, from 1967 through 1981, with a minimum five-year follow-up. In 1982 we reported[4] a longer-term survey of the presentation and anatomical location of gastric adenocarcinoma in patients at the Lahey Clinic that covered the 40-year span from 1940 to 1980, and for the first time described a marked increase in the rate of a proximal location for gastric cancer and a corresponding decrease in the rate of a distal location. The present study further substantiates the changes in histologic pattern, location in the stomach, and surgical therapy, and describes current results of operative treatment in gastric adenocarcinoma.

Accepted for publication Oct 23, 1987.

PATIENTS AND METHODS

All 211 cases of gastric adenocarcinoma recorded at the Lahey Clinic Foundation from 1967 through 1981 were reviewed, histologic material was reevaluated, and current status was determined. Lauren's histologic classification,[5,6] which defines lesions histologically as being of the "diffuse," "intestinal," or "mixed" type, was used. A small "other" group was recorded in which only biopsy material was available, with the lesion type remaining undefinable.

Three types of gastric adenocarcinoma presented at diagnosis. *Superficial gastric adenocarcinoma* was defined when malignant cells failed to penetrate beneath the muscularis propria. *Infiltrative gastric adenocarcinoma* (linitis plastica) was defined by the presence of malignant cells diffusely spread through a thickened gastric wall with a desmoplastic reaction and a typical clinical pattern. *Focal gastric adenocarcinoma* with a polypoid, fungate, or ulcerative appearance was defined when there was no extensive thickening of the gastric wall, no desmoplastic reaction, no wide lateral spread beneath the mucosa, and the cancer invaded through the muscularis propria. These three distinctive types can also be readily identified clinically.

Distal gastrectomy was defined as any operation that preserved a proximal portion of stomach and did not construct a proximal anastomosis to the esophagus. *Total gastrectomy* was defined as an operative specimen that included duodenum distally and esophagus proximally. *Esophagogastrectomy* was defined by the presence of esophagus at the proximal margin and stomach at the distal margin of the specimen. These operative categories separated the inherently more dangerous esophageal anastomoses and allowed us to address the continuing conflict regarding total gastrectomy as a manifestation of the extensiveness of local cancer removal in the stomach.

Location within the stomach was defined as *distal* if it arose in the distal one third of the stomach by analysis of radiology and endoscopy reports as well as operative notes and pathology reports. *Proximal* gastric cancer occurred in the proximal one third of the stomach, which included the cardia, upper lesser curvature, and fundus. Adenocarcinomas of the *body* of the

*Of 31 patients who survived five years, four (13%) later died of disease.

stomach were located in the middle one third of the stomach and were undoubtedly an admixture of the distinctive proximal and distal types.

Curative resections were defined as the absence of gross residual disease at the conclusion of the surgery, while *palliative* resections left gross residual disease at completion, as recorded by the surgeon. The presence of a microscopically positive margin in the final pathology report did not change the designation of curative resection.

Operative mortality occurred when a patient died without leaving the hospital after surgery.

Only one patient (0.5%) was unavailable for follow-up less than five years after surgery and was considered dead of disease. This 99.5% follow-up provides assurance that the conclusions represent true clinical results. Postoperative deaths (five, 2.8%) were recorded as patients dead of disease.

Results will be presented in a fashion similar to that of our previous reports to enable estimation of time trends and provide direct comparisons. Where results of our initial study were also well substantiated in these patients and by other articles in the literature, further data are not reported. Thus, symptomatology, clinical presentation, and survival in relation to size, gastric wall penetration, number of lymph node metastases, and stage do not differ from our previous[3] and other recent reports.[7]

RESULTS

Results are not presented in the tumor-nodule-metastases (TNM) staging system because cases for the most part were treated before the system for stomach cancer had been accepted; the TNM system would have been inaccurate if applied retrospectively, particularly when describing the location of lymph node metastases. Furthermore, the present series emphasizes several features of gastric cancer that are important to prognosis, yet are not recognized by the current TNM system, such as location within the stomach (proximal vs distal), number of lymph node metastases (rather than their location relative to the stomach), histologic type (Lauren's classification), pattern of growth (linitis plastica), whether all disease could be resected (curative vs palliative resection), and the type of resection (conservative vs total gastrectomy).

Two hundred eleven documented cases of gastric adenocarcinoma were histologically confirmed at the Lahey Clinic Foundation from 1967 through 1981. Thirty-five cases (17%) were not explored because endoscopic biopsy documented the histologic diagnosis and the patients had evidence of metastatic disease, extensive intraperitoneal

spread, hopelessly advanced local growth, or linitis plastica without symptoms requiring surgery. One patient had a biopsy specimen that confirmed superficial gastric adenocarcinoma but he died of advanced prostate cancer one month later without surgery for the obviously operable gastric cancer. This rate of inoperability was three times that noted in our earlier study (17% vs 6%) and undoubtedly reflects wider use of flexible endoscopic techniques with biopsy confirmation, compared with the infrequently used rigid gastroscopic biopsy available before 1967.

Infiltrative gastric adenocarcinoma (linitis plastica) was defined in 32 cases (15%). Focal (polypoid, fungating, or ulcerated) gastric cancers occurred in 167 cases (79%) (Table 1). These types were essentially identical in incidence to the 16% and 81% reported between 1957 and 1966.[3] Superficial gastric cancers were diagnosed in 12 patients (6%), a substantial rise from 3% of cases previously noted.[3] Table 1 demonstrates the curative resection rate and the cure rate in these patients. For the remaining patients, rates of palliative resection and laparotomy and biopsy are shown, as well as the median survival duration in months for patients who *died*. All patients with superficial gastric cancer who were operated on underwent resection, and ten of the 11 were cured. One patient died nine months after resection in unusual circumstances and while he was officially declared dead of gastric cancer, no autopsy was performed and no clinical evidence on hospital chart review at the time of death indicated recurrent, metastatic, or persistent gastric cancer; serious doubt exists that such failure occurred.

In the cases categorized as infiltrative (linitis plastica) or focal gastric adenocarcinoma, only 13% and 34%, respectively, of patients operated on underwent curative resection, a marked decline from our previous report in which 43% and 46%, respectively, were so defined. The median survival of these patients who eventually died of disease was 12 months and 38 months, respectively, compared with 14 months and 19 months previously. Palliative resections were carried out in 28% and 25% of cases, respectively, of infiltrating and focal gastric cancers in patients taken to surgery, a sharp increase compared with the previous study. The combined resection rates of all patients taken to surgery for infiltrative cancers decreased from 51% in the earlier study to 45% in the present study, but rose from 63% to 72% for focal cancers, reflecting better understanding of the outcome in linitis plastica and elimination of some candidates for exploration by wider use of endoscopy.

No patients died postoperatively after the 72 curative resections performed, and only two deaths (4%) occurred following the 50 palliative resections, for an overall mortality rate for gastric resections of 1.6%. There were three deaths (6%) among 54 patients who underwent laparotomy, for an overall operative mortality rate of 2.8% in 176 patients who underwent exploration. The postoperative mortality rate for gastric resection of 10% between 1957 and 1966 was thus sharply improved, as was the overall operative mortality rate (6.4% vs 2.8%) in all patients undergoing exploration.

Table 2 describes the outcome in patients undergoing curative resection of focal gastric cancer. Patterns of disease progression and survival rates after resection are best portrayed in the focal cancer group undergoing curative resection, since all patients with superficial gastric cancers survived and all patients with infiltrative cancers or palliative resection died of disease. The proportion of patients undergoing either total gastrectomy (4%) or esophagogastrectomy (12%) declined from our earlier series (14% and 29%, respectively), reflecting a more conservative attitude toward the use of total gastrectomy and the

more selective use of esophagogastrectomy. Almost three fourths of distal, but only 42% of proximal, cancers could be resected. Our previous study noted that 24% of patients surviving five years eventually died of disease, while in the present study 13% of patients who were alive at five years eventually died of disease. No patients free of disease at this writing were expected to later die of gastric cancer because all 27 such patients had been followed up for more than six years. Three of the four patients who did die of disease after five years died in the sixth year. Thus, with few exceptions, six-year disease-free survival is tantamount to cure.

The rate of patients with proximal cancers undergoing curative resection was one half that of patients with distal gastric cancers (Table 3), and cancers in nearly one half of all patients undergoing exploration but not resection had a proximal location.

Lymph node metastases are important prognostic indicators. Forty-six percent of patients with negative nodes were cured, while 30% of those with one to three nodes, 16% of those with four to ten nodes, but none of those patients with more than ten node metastases were cured. However, whether the resection was classified as curative or palliative was of far more importance, since 49% of the patients with curative resections but none of those with palliative resections were cured. The number of lymph node metastases in palliative resections may not have been accurate since nodes left at the conclusion of surgery may have been the criterion for incomplete resection.

Table 4 illustrates the continuing increase in "diffuse histology" associated with a worse prognosis, as illustrated by its decreasing relative proportion as resection is performed; disease in 55% of patients undergoing biopsy only showed diffuse histology, but only 42% of cases with curative resections did. In contrast, 26% of patients undergoing biopsy only, but 46% of cases with curative resections, are classified as showing intestinal histology. While diffuse histology generally presents in a more advanced fashion and stage-for-stage carries a worse prognosis, of the 24 patients undergoing curative resections for focal gastric cancer classified as showing diffuse histology, 12 (50%) were cured. Thus, given the appropriate clinical presentation, diffuse histology by itself in no way indicates incurability.

There is a unique male predominance (4:1) in the sex ratio of proximal location, in contrast with distal gastric adenocarcinomas (1.2:1). Among focal cancers, the same unique sex ratio can be demonstrated; proximal cancers predominate among male patients (4:1), while distal cancers are equally distributed (1:1). Table 5 shows the changing anatomical location of gastric adenocarcinoma within the stomach since 1940. The three decades presented in the first columns are taken from our previous report[3] and the last column represents the present series. The sharp decline in the rate of distally located gastric cancers has continued while proximally located gastric cancers now constitute more than one third of cases. Table 6 offers a hypothetical extrapolation from the record of changing gastric adenocarcinoma incidence overall coupled with the relative change in location within the stomach. This theoretical model illustrates the extraordinarily rapid disappearance of distal gastric adenocarcinoma, in contrast with the far more modest decline in the absolute incidence of proximal and body cancers.

Table 7 illustrates the time trends in the surgical approach to gastric adenocarcinoma over five decades at the Lahey Clinic. The significant trends noted are the recent decrease in the rate of exploration and curative resections and the increasing rate of palliative resections. For the first time, a significant increase in five-year survival rates is noted, with an approximate doubling of the previously low rates in all cases diagnosed, all cases resected, and all cases undergoing curative resection.

COMMENT

Gastric adenocarcinoma continues to represent an oncologic and surgical challenge; in a 1977 report we[3] noted no improvement in the five-year survival rate over four decades. Other reports documented similar discouraging results.[7-11] Because we noted[4] changes in clinical presentation previously unrecognized but subsequently documented by others,[12,13] we undertook the present study to substantiate the increasing proportion of proximal gastric adenocarcinoma and diffuse histology (Lauren). Both trends have continued and call attention to the fact that gastric adenocarcinoma is not a single pathologic, clinical, or epidemiologic entity. For instance, while seldom separately reported in the United States, superficial gastric adenocarcinoma (also termed "early gastric cancer," but implications of duration in that description should be avoided) represents a distinct clinical entity,[14] with virtually all cases cured by relatively conservative distal gastric resections.[15-17] In the TNM staging system, such cases are categorized as T1 and, since node metastases are seldom detected, N0, and therefore are in stage 1. However, these cases may represent a unique biologic situation and not just an early stage. Such cases occasionally recur in the mucosa and can frequently be cured by further excisions, as one of our patients illustrated; such patients should undergo yearly follow-up endoscopy. In Japan, gastric adenocarcinoma is common; population screening by endoscopic surveillance has resulted in superficial involvement only (T1) in as many as 30% of all cases diagnosed[18] and represents a successful public health strategy. Such screening probably could not be justified in the United States because of the low incidence and high cost.

The rise in the rate of superficial gastric adenocarcinoma from 3% to 6% in our series and in other American reports[9,11,19] may be a result of the wider use of endoscopy and biopsy. The clinical course, duration, and natural history of superficial gastric adenocarcinoma are not yet well described, but the period between superficial involvement and invasive focal adenocarcinoma can be speculated on.[20] In 12 cases of superficial gastric adenocarcinoma, all but one was of an intestinal histology, and these patients had a median age of 61 years, while the median age of the 64 patients with focal cancer of intestinal histology was 67 years. Such a six-year lag time is consistent with time periods from in situ presentation to presentation with invasive clinical cancers occurring in the colon, cervix, and breast, and in melanoma.

The Lauren classification of gastric adenocarcinoma histologic types has proved useful since the two major types represent groups of patients with differing ages, sex ratios, survivals, epidemiology, and apparent origin.[6] Other reports[6,21,22] have noted a rise in the relative proportion of cases with diffuse histology from approximately 35% in the 1940s, to 45% in the 1960s, to almost 60% in the 1970s, at a time when the overall number of cases is decreasing. Patients whose cases are of diffuse histology tend to be younger,[23-25] with a slight predominance among women, and these cases have a relatively stable absolute incidence over time that produces the proportional increase in incidence. These trends have been exhaustively researched and summarized by Correa.[6] While the most marked clinical manifestation of the diffuse histologic pattern is the linitis

plastica clinical type, which is easily recognized radiologically or surgically, many focal cases also have diffuse histology; these patients too have a slightly worse overall prognosis,[3] but their disease is curable if completely resected. Linitis plastica occurred in exactly the same proportion of cases as in our earlier report,[3] despite the proportional increase in diffuse histology. These facts suggest that linitis plastica is a peculiar host response to the cancer cells rather than just a unique histologic entity. Patients with linitis plastica all die of disease, usually after a short survival, but a few patients live for prolonged periods. Thus, all treatment of linitis plastica must be viewed as palliative. Indeed, the median survival of the few patients (14%) undergoing curative resection is no longer than that of patients undergoing palliative resection (12 months and 13 months, respectively). If resection is possible and safe, it probably should be attempted, but surgery may be avoided if obstruction or bleeding are not present.

Intestinal histology is seen in patients who have diet-related distal adenocarcinoma; thus, this manifestation is gradually declining in absolute incidence and overall relative proportion, both in the United States and in Europe.[6] Intestinal histology is seen in almost all superficial and many focal gastric cancers, and is more heavily represented in earlier and resectable cases.

The changing anatomical location of gastric adenocarcinoma reflects a little-noted trend that has an impact on the diagnosis and management of the disease. First reported by us in 1982,[4] other authors have documented a similar trend toward proximal location.[7,11-13] Proximally located gastric adenocarcinoma is marked by a relatively stable absolute incidence over time (in contrast with distal lesions), by a marked male predominance,[26] and by a generally worse prognosis. Despite some similarity of trends in diffuse histology (stable absolute incidence, increasing relative proportion, and worse prognosis), there are substantial differences (male predominance). Proximally located cancers are largely of intestinal histology and arise frequently on a background of dysplastic mucosa, indicating prolonged antecedent changes. These antecedent mucosal dysplasias frequently have produced hypochlorhydria or achlorhydria and proximally located cancers are marked by significantly elevated levels of serum gastrin as a result, in contradistinction to distally located cancers in which gastric acid is produced and serum gastrin levels are normal.[27]

Gastric stump adenocarcinomas,[28,29] those cancers arising in stomachs previously partially resected distally for benign duodenal ulcer, by definition are of the proximal type, and display the characteristics of proximal gastric cancers arising in intact stomachs (striking male predominance, hypochlorhydria, dysplasia of gastric mucosa, elevated gastrin levels, and poor prognosis). Although gastric stump adenocarcinomas are considered to be caused by the bile gastritis occurring with jejunal anastomoses to the stomach, we postulate that their incidence is similar to what would be expected in the population of at-risk patients followed up over the long term after ulcer operations. The more modern surgical therapy of duodenal ulcer without gastric resection has been used frequently only during the past decade; since the average lag period between gastrectomy and stump carcinoma is prolonged, it will be many years before we learn whether the preservation of the distal stomach, and even the pylorus, with reduced acid production from vagotomy but without bile gastritis, will be associated with the formation of proximal gastric adenocarcinomas.

The rising relative incidence of proximal adenocarcinoma highlights the rapid disappearance of distally located gastric cancers, which are clearly diet related, as noted by Correa.[6] Distally located cancers are "epidemic" in nature, and are related to dietary variations, while the proximal location is "endemic," as is diffuse histology. Thus, the decline in the incidence of distally located tumors in the United States has unmasked the endemic varieties, bringing them under investigation. Since significant adjustments in basic surgical approaches must be made for the treatment of proximally located cancers, and esophagogastrectomy is inherently more difficult, it was encouraging to note the sharp reduction in operative mortality. Currently, proximal gastrectomy and total gastrectomy can be performed with negligible operative mortality. The use of the circular stapling device had nothing to do with the results reported herein, since it was not used. Because proximal cancers may be resected via a transthoracic approach, members of general surgical services may have even less gastric adenocarcinoma experience than would be expected from incidence data; however, nearly all such cancers can be as effectively approached from the abdomen, with only an occasional need to open the chest for resection of esophageal extension, and thus their treatment should be within the competence and experience of surgical oncologists.

The overall resection rate has remained remarkably stable since 1950, while shifts in the proportions labeled palliative or curative have changed, reflecting changed attitudes regarding extensive lymph node resections for nodal metastases at some distance from the stomach and attempts to remove all direct spread to adjacent structures. Generally more conservative surgical approaches have been practiced since 1970. Routine sacrifice of the spleen, omentum, pancreas, and celiac nodes was infrequently performed and was used only in a highly selective fashion. Surgeons were less likely to attempt removal of extensive local evidence of disease once the primary gastric cancer and stomach were removed by gastrectomy when the goal was only palliation. The total gastrectomy rate was 13% of all resections and only 4% of curative resections, in contrast with the 14% rate reported in the 1960s, and over 30% reported in the 1950s, thus indicating a continued decline in the routine use of this procedure. Total gastrectomy was used only when indicated by the local extent of the disease in the stomach itself. This was illustrated by the fact that 26% of all patients undergoing palliative resection and 72% of all patients undergoing resection for linitus plastica required total gastrectomy.

The principal palliative goal is to rid the patient of the infected, bleeding, obstructed, necrotic, or ulcerated polypoid gastric lesion. For this purpose a limited gastric resection may suffice. Extension of the resection to other organs only occasionally cures the patient and sometimes does not justify the morbidity for a palliative goal. That such a conservative operative policy is practical and important is reflected in the median survival values of palliative cases, the sharply decreased operative mortality, the improved five-year survival rates for patients who undergo resection for cure, and the survival durations of patients who undergo curative resections but who nevertheless die of disease. Compared with our previous report, palliative resections bring about an improved median survival, partly reflecting the decreased operative mortality, but also reflecting the decreased morbidity and mortality of more restricted operations. A conservative surgical philosophy has yielded similar therapeutic benefits with other cancers.

Our better five-year survival and cure rates indicate that

a policy of routine total gastrectomy, as advocated by some authors,[27,28] is unnecessary and dangerous. Vigorous attempts to remove the cancer itself, along with a modest amount of surrounding uninvolved gastric wall encompassing the gross tumor, should be performed to produce an intact gastrointestinal tract. Previously we noted that the resection margin of normal stomach was not the determining factor in outcome. Thus, a reasonable local gastric margin of 3 to 4 cm should be sought,[29] but compromises are frequently required. Carcinoma that is evident at a distance from the primary cancer need not be resected, since such diseased tissue is associated with a fatal outcome regardless of its resection. Maximum potential palliation is achieved by clearing the gastrointestinal tract of the primary cancer.

The present study documents significant changes in the clinical and pathologic presentations of gastric adenocarcinoma. It also documents the benefits of a generally conservative surgical philosophy and indicates a surprising improvement in outcome as measured by median and five-year survival rates. Surgeons need to recognize these changes and transitions in disease to tailor properly their surgical therapy.

Cardiopulmonary Resuscitation in Patients With the Acquired Immunodeficiency Syndrome: A Prospective Study

Mario C. Raviglione, MD; Ruggero Battan, MD; Angelo Taranta, MD

To study the outcome of cardiopulmonary resuscitation (CPR) in patients with acquired immunodeficiency syndrome (AIDS), data on CPR in hospitalized patients were collected prospectively during a one-year study period. Of 43 consecutive patients with AIDS who underwent CPR, 23% were revived in the initial attempt, whereas of 293 patients with other diseases 42% were revived. One (2.3%) of 43 patients with AIDS survived until hospital discharge, and his arrest was iatrogenic, as opposed to 19 (6.5%) of 293 patients with diseases other than AIDS. A respiratory mechanism for the arrest was significantly more common in patients with AIDS. The duration of the unsuccessful attempt did not vary significantly; a higher number of temporary pacemakers was used in patients with diseases other than AIDS indicating a more invasive approach. Survival until hospital discharge is minimal in our series of patients with AIDS, undergoing CPR. We recommend that informative discussions take place early in the course of the disease to provide patients with a better understanding of the available options in case of cardiorespiratory arrest (*Arch Intern Med* 1988;148:2602-2605).

Is Extensive Lymphadenectomy Necessary for Surgical Treatment of Intramucosal Carcinoma of the Stomach?

Keiji Iriyama, MD; Toyomatsu Asakawa, MD; Hiroshi Koike, MD; Hiroshi Nishiwaki, MD; Hiroshi Suzuki, MD

• This study was undertaken to elucidate those histological and gross features associated with gastric carcinoma that can be adequately treated by gastrectomy with less aggressive lymphadenectomy. The frequency of metastasis to the lymph nodes was analyzed in 514 cases of resected, solitary, gastric carcinomas. The frequency of metastasis to the lymph nodes increased in proportion to the increase in the extent of penetration by the cancer into the gastric wall. Lymph nodes were not involved in cases of intramucosal carcinoma of the intestinal type, by Laurén's histological classification. By contrast, metastasis to the lymph nodes was observed in cases of intramucosal carcinoma of the diffuse type, by Laurén's classification. We conclude that extensive lymphadenectomy is not mandatory for patients with intramucosal carcinoma of the stomach of the protruded type, since the lymph nodes do not become involved in this type of gastric carcinoma.

(*Arch Surg* 1989;124:309-311)

Extensive lymph node dissection in the surgical treatment of patients with carcinoma of the stomach has been advocated by Japanese surgeons[1-3] and has been adopted by surgeons all over the world. Since the intraoperative decision of whether or not the lymph nodes are involved is often inaccurate, extensive prophylactic lymphadenectomy seems to be necessary for the surgical treatment of patients with gastric carcinoma. However, the frequency of metastasis to the lymph nodes in patients with intramucosal cancer is extremely low and has been reported as varying from 1.9% to 7%.[4-8] Thus, we need to reconsider whether extensive lymphadenectomy is necessary for all patients with adenocarcinoma of the stomach, regardless of the extent of cancer. The present study was undertaken to elucidate the specific types of gastric carcinoma in which lymph nodes are not involved.

PATIENTS AND METHODS

From July 1, 1973, through Dec 31, 1986, there were 684 patients with primary adenocarcinoma of the stomach admitted to our clinic. Of these 684 patients, 553 (80.8%) underwent gastric resections. Thirty-nine patients with synchronous multiple carcinomas in the stomach were eliminated, so that the present analysis is based on the remaining 514 cases of resected stomachs. The operative mortality was 1.1%. The gross appearance of the carcinomas was classified into two principal types: the protruded type and the depressed type (Figure). The protruded type includes types I and IIa in the Japanese classification for early gastric cancer, and type 1 in Borrmann's classification. The depressed type includes types IIb, IIc, and III in the Japanese classification for early gastric cancer, and types 2, 3, and 4 in Borrmann's classification.[9] Most importantly, even if the principal gross feature of the cancer corresponded to the protruded type, any cancer that included even a minute ulceration, erosion, or excavation in the lesion was classified as the depressed type in the present study. The histological type was determined according to the report of the Japanese Research Society Committee on Histological Classification of Gastric Cancer,[10] and was classified into Laurén's classification as shown in Table 1. Papillary, well-differentiated, and moderately differentiated adenocarcinomas were classified as the intestinal type in Laurén's classification.[11] Poorly differentiated adenocarcinomas and signet-ring cell carcinomas were classified as the diffuse type in Laurén's classification. Because mucinous carcinomas were found to have structural characteristics in common with both the intestinal and the diffuse type, they were classified as being of the intestinal and the diffuse type by their structural features. One type, classified as the intestinal type, had distinct, usually large glandular lumina that were dilated and split by a profuse pool of mucus in which they floated. The other type had mucous masses that accumulated around isolated cells or loose clusters of cells and was classified as the diffuse type. Adenosquamous carcinomas were found mostly to be of the intestinal type.

Macroscopic classification of early gastric cancer and Borrmann's classification of advanced gastric cancer, and corresponding classification of present study. Shaded area represents malignant tissue.

Table 1.—Histological Classification of Gastric Cancer

Japanese Research Society Committee on Histological Classification of Gastric Cancer	Laurén's Classification	General Structure
Papillary adenocarcinoma Tubular adenocarcinoma Well-differentiated type Moderately differentiated type	Intestinal type	Large glandular lumina; papillary fold formation; glandular structure is rarely completely absent
Poorly differentiated adenocarcinoma Signet-ring cell carcinoma	Diffuse type	Cells are found to be scattered; glandular lumina are rarely seen; cells seem to be only loosely attached to one another, forming no distinct epitheliumlike cords

Table 2.—Postoperative Five-Year Survival in Relation to Depth of Cancer Invasion*

Depth of Invasion	No. of Patients	Five-Year Survival Rate, %
ps(−)		
m	82	93.8
sm	84	86.4
pm	53	78.1
ss	36	66.9
ps(+)	259	31.0
Curative resection	146	52.9
Palliative resection	113	4.1

*ps(−) indicates negative prognostic serosal invasion; m, intramucosal; sm, submucosal; pm, muscularis propria; ss, subserosal; ps(+), cancer cells present on the serosal surface and exposed to the peritoneal cavity.

Cancers whose deepest layer of invasion into the gastric wall was the tunica mucosa including muscularis mucosae, tela submucosa, tela muscularis propria, and tela subserosa were included in the category of ps(−) cancers (negative prognostic serosal invasion). Any cancer whose deepest invasion was present on the serosal surface and that was exposed to the peritoneal cavity was classified as ps(+) cancer. Ulceration or resultant scars were analyzed microscopically. For the histologic examination of lymph nodes, one slice of all dissected lymph nodes, obtained by a cross section through the hilus at the central portion of each of the dissected lymph nodes, was examined. The cumulative crude survival rates were calculated by the Kaplan-Meier method. The significance of the distributions of the samples was evaluated by the χ^2 method. In the text, significant indicates $P<.05$.

RESULTS

Two hundred fifty-five patients with the ps(−) cancers (49.6%) were identified among the 514 patients. The postoperative five-year survival rates in relation to the depth of invasion of the gastric wall are given in Table 2. The five-year survival rate was 93.8% in cases of intramucosal cancer, 86.4% in cases of submucosal cancer, 78.1% in cases of cancer of the muscularis propria, 66.9% in cases of subserosal cancer, and 31.0% in cases of ps(+) cancer. Curative gastric resection was performed in 146 of the 259 patients with ps(+) cancer, and the five-year survival rate was 52.9%, compared with 4.1% in the 113 patients who underwent palliative resection.

Table 3 gives the relationship among the depth of invasion, the histological type, and the frequency of lymph node metastasis. The frequency of lymph node metastasis increased proportionately to the extent of penetration by the cancer into the gastric wall: four (4.9%) of 82 in cases of intramucosal cancer; 14 (16.7%) of 84 in cases of submucosal cancer; 21 (39.6%) of 53 in cases of cancer of the muscularis propria; 25 (69.4%) of 36 in cases of subserosal cancer; and 231 (89.2%) of 259 in cases of ps(+) cancer. However, lymph node metastasis was absent in all patients with intramucosal cancer of the intestinal type. The frequency of lymph node metastasis in patients with intramucosal cancer was significantly higher in cases of the diffuse type of cancer than in cases of the intestinal type ($P<.05$). The histological types did not influence the frequency of metastasis to the lymph nodes in cases with more extensive invasion by the cancer.

Table 3.—Relationship Among Depth of Cancer Invasion, Histological Type, and Lymph Node Metastasis in Gastric Adenocarcinoma*

Depth	Histological Type, Lymph Node Metastasis	Negative	Positive	Subtotal	Total
ps(−)					
m	Intestinal	44 (100)	0 (0)	**44 (100)**	**82** (16.0)
	Diffuse	34 (89.5)	4 (10.5)	**38 (100)**	
sm	Intestinal	35 (79.5)	9 (20.5)	**44 (100)**	**84** (16.3)
	Diffuse	35 (87.5)	5 (12.5)	**40 (100)**	
pm	Intestinal	18 (64.3)	10 (35.7)	**28 (100)**	**53** (10.3)
	Diffuse	14 (56.0)	11 (44.0)	**25 (100)**	
ss	Intestinal	7 (31.8)	15 (68.2)	**22 (100)**	**36** (7.0)
	Diffuse	4 (28.6)	10 (71.4)	**14 (100)**	
ps(+)	Intestinal	11 (10.5)	94 (89.5)	**105 (100)**	**259** (50.4)
	Diffuse	17 (11.0)	137 (89.0)	**154 (100)**	
Total	...	...	...	...	**514 (100)**

*Values are number (percent). ps(−) indicates negative prognostic serosal invasion; m, intramucosal; sm, submucosal; pm, muscularis propria; ss, subserosal; ps(+), cancer cells present on the serosal surface and exposed to the peritoneal cavity. Frequency of metastasis to lymph node in mucosal carcinoma is significantly low in the intestinal type as compared with the diffuse type ($P<.05$).

Table 4.—Clinicopathological Features of Mucosal Carcinoma of the Stomach With Lymph Node Metastasis*

Patient No./ Age, y/Sex	Maximum Diameter, cm	Lymph Node Involved
1/53/F	6.2	Infrapyloric
2/48/F	7.8	Lesser curvature
3/40/F	5.0	Lesser and greater curvature
4/41/F	7.5	Lesser curvature, infrapyloric

*In each case the cancer was the depressed, diffuse type, associated with ulceration.

In the present series, four patients had intramucosal cancer with involvement of the regional lymph nodes, and their clinicopathological characteristics are given in Table 4. The common pathological features of their cancers were as follows. All were of the diffuse, depressed, superficially spreading type with maximum diameter more than 5 cm, and all had accompanying ulceration or resultant scars within the cancer. Metastasis was observed in the perigastric lymph node in these four patients.

Table 5 gives the relationship between the histological

Table 5.—Relationship Between Histological Type and Gross Appearance of Early Gastric Cancer*

	Depressed Type	Protruded Type
Intestinal type	71 (47.7)	17 (100)
Diffuse type	78 (52.3)	0 (0)
Total	**149 (100)**	**17 (100)**

*Values are number (percent).

Table 6.—Accuracy of Preoperative Assessment of Invasion in the Depressed Type of Early Gastric Carcinoma*

	Depth	
Assessment	**m**	**sm**

sm	12	68
Accuracy, %	80.6	78.2

*m indicates intramucosal; sm, submucosal.

type and the gross appearance of early gastric cancer. The histological type of the protruded carcinomas was the intestinal type, without exception.

Table 6 gives the results of preoperative assessment of the depth of invasion by the cancer, in patients with the depressed type of early gastric cancer, by an upper gastrointestinal roentgenographic series and by endoscopic examination. We incorrectly assessed the depth of invasion in 20.8% of the patients with the depressed type of early gastric carcinoma. By contrast, we correctly assessed the depth of cancer invasion in all patients with the protruded type of early gastric carcinoma.

COMMENT

The prognosis of early gastric cancer is generally excellent, and the five-year survival rate has been reported to be greater than 90%. Certainly, the excellent five-year survival rate may be associated with treatment by gastrectomy with extensive lymphadenectomy.

Until two years ago, our surgical treatment for curatively resectable carcinoma of the stomach also included extensive lymphadenectomy with combined resection of the bursa omentalis, regardless of the extent of cancer. Since it is not unusual to observe metastasis to lymph nodes in cases of early gastric carcinoma, it seems reasonable to perform extensive lymphadenectomy uniformly in all patients with gastric carcinoma, regardless of the extent of cancer. The incidence of metastasis to lymph nodes in patients with early gastric cancer has been reported as varying from 1.9% to 7% in cases of intramucosal cancer, and from 7.4% to 20.9% in cases of submucosal cancer.[4-7,11] In the present study, the frequency of metastasis to lymph nodes was 4.8% in cases of intramucosal cancer, and 16.7% in cases of submucosal cancer. Because of these data, we do not criticize the performance of extensive lymphadenectomy in patients with gastric carcinoma that penetrates beyond the submucosal layer. However, in cases in which the gross and histological features of the intramucosal gastric carcinoma completely exclude the possibility of metastasis to lymph nodes, extensive lymphadenectomy with complete removal of the bursa omentalis is not necessary.

Korenaga et al[6] reported the clinicopathological features of 11 cases of intramucosal carcinoma with lymph node metastasis from a total of 568 patients with intramucosal carcinoma of the stomach. The histological classification of the tumor in nine of their 11 patients was the diffuse type, and ten patients had the depressed or flat type of tumor. They reported one case of a pure protruded type of intramucosal carcinoma of the intestinal type, in which the lymph node along the lesser curvature was involved. The size was 5.0×1.9 cm. This case is probably the first published case of metastasis to a lymph node seen in a case of a protruded type of intramucosal cancer of the intestinal type.

In the current study, the frequency of metastasis to the lymph nodes in cases of intramucosal cancer of the intestinal type was nil. However, we demonstrated that the differentiation, in terms of the depth of cancer invasion, between intramucosal and submucosal is often inaccurate in the depressed type of early gastric cancer. Consequently, four histological or gross features have ultimately emerged as the characteristics that eliminate the likelihood of metastasis to a lymph node: (1) intramucosal cancer, (2) the protruded type, (3) the intestinal type, and (4) a maximum size of less than 5 cm in diameter. An endoscopic feature of the cancer that satisfies the above-mentioned characteristics is a pure protruded type of cancer; in other words, the protruded type of cancer showing neither erosion nor excavation in the cancer, with a maximum diameter of less than 5 cm. The histological type of cancer demonstrating these characteristics is the intestinal type without exception, and the penetration of cancer into the gastric wall is probably confined to the mucosal layer. Lymph node is not involved in such a lesion. Thus, precise preoperative endoscopic evaluation is mandatory.

We conclude that gastrectomy with less aggressive lymphadenectomy may suffice as the curative surgical treatment for gastric cancer having the characteristics described above. The less aggressive lymphadenectomy that we emphasize in the current study is an operative procedure that includes dissections of the right cardial lymph node, the lymph nodes along the lesser and greater curvature, and the suprapyloric and infrapyloric lymph nodes, and preservation of the posterior portion of the bursa omentalis, ie, the capsule of the pancreas and the peritoneum around the common hepatic and splenic arteries. As the right and left omental arteries are resected, a combined removal of the greater omentum is therefore mandatory.

Surgeon
Dallas

CIGNA Healthplan, one of the nation's largest investor-owned health maintenance organizations, is seeking a general or vascular surgeon to join the Dallas Plan as Department Chair. We are seeking a surgeon with superior clinical and leadership skills to join two other surgeons in a busy practice serving over 50,000 members. The Department Chairman will coordinate delivery of surgical services, as well as lead through example in hospital and office practice.

For the exceptionally qualified physician, we offer:

- A Generous Compensation Package
- Predictable Schedule
- Generous Vacation and Educational Leave
- Paid Malpractice Insurance
- An Opportunity to Shape the Future of Health Care

For confidential consideration, send your C.V. to **Carolyn Pabich, Dept. INT., CIGNA Healthplan of Texas, Inc., P.O. Box 542588, Dallas, TX 75354-2588, or phone (214) 401-5303.**

THE NATURAL CHOICE

GORE-TEX® SOFT TISSUE PATCH

In reconstructive surgery, a patient's own tissue is not always adequate. However, today surgeons do have alternatives. When a biomaterial is indicated, the GORE-TEX Soft Tissue Patch is the natural choice.

This remarkable sheet of GORE-TEX (expanded polytetrafluoroethylene) is engineered to provide improved performance in a wide range of applications. Since its introduction in 1982, the GORE-TEX Soft Tissue Patch has been used in more than 50,000 clinical cases worldwide.

The GORE-TEX Soft Tissue Patch combines high, balanced strength with softness and conformability. It is easy to shape and contour without fraying. Its microporous structure allows natural tissue ingrowth leading to potential treatability in the presence of infection. Next to delicate internal organs, the GORE-TEX Soft Tissue Patch has shown a significant reduction in adhesion formation and tissue erosion.

The exceptional versatility of the GORE-TEX Soft Tissue Patch makes it the natural choice in a wide range of applications.

- Abdominal Wall Reconstruction
- Hernia Repair
- Thoracic Wall Reconstruction
- Diaphragm Reconstruction
- Rectal and Vaginal Suspension
- Urethral Suspension
- Gastric Banding
- Facial Augmentation and Sling Procedures
- Related Pediatric Reconstructions

☐ Please send further information on the GORE-TEX Soft Tissue Patch.
☐ Please arrange for a free clinical sample.
☐ Please have your sales representative call for an appointment.

DNA Ploidy and Tumor Invasion in Human Gastric Cancer

Histopathologic Differentiation

Daisuke Korenaga, MD; Masaru Haraguchi, MD; Takeshi Okamura, MD; Hideo Baba, MD; Atsushi Saito, MD; Keizo Sugimachi, MD

• The relationship between DNA ploidy and tumor invasion in 254 patients with gastric carcinoma was studied, with particular emphasis on histopathologic features. In the differentiated type of adenocarcinoma, there were aneuploid lesions characterized by a relatively high incidence of lymph node metastasis and hematogenous recurrence, even when the invasion was limited to the submucosa. In the undifferentiated type, aneuploid lesions were rarely seen at the early stage, but the frequency remarkably increased with invasion into the deeper layers. Nodal involvement and disseminating metastasis were evident with serosal invasion. Analyzed by a multivariate Cox model, DNA ploidy significantly correlated with prognosis. Thus, DNA ploidy is a major determinant of survival, and the behavior of an aneuploid carcinoma is apparently controlled by individual histologic type.

(*Arch Surg* 1989;124:314-318)

Numerous DNA studies on human solid tumors revealed an association between the poor prognosis and abnormal DNA content.[1-3] This DNA abnormality corresponded to poorly differentiated tumors, as in carcinoma of the bladder, prostate, and breast,[3-5] but not always to cases of gastric carcinoma. Most recurrences in early carcinoma are those in which the lesion is well and moderately differentiated.[6,7] Cytophotometric DNA analysis of gastric carcinoma revealed that the differentiated type (DT), including well-differentiated and moderately differentiated adenocarcinomas, frequently had a dominant DNA distribution in the aneuploid range. The undifferentiated type (UT), consisting of poorly differentiated adenocarcinoma and signet-ring cell carcinoma, was predominantly of the diploid pattern.[8-10] While it is generally agreed that the UT has a favorable prognosis at the early stage of disease, some do become the highly malignant type of advanced carcinoma, characterized by rapid growth and by a poor prognosis.[11,12] This paradox suggested to us that the relationship between tumor progression and DNA abnormality, especially in cases of UT, had to be given attention.

The present study concerns progression of gastric carcinoma, with special focus on DNA abnormalities and histopathologic features.

Accepted for publication Feb 18, 1988.

PATIENTS AND METHODS

Patients

This study was based on 254 patients with gastric carcinoma treated in the Department of Surgery II, Kyushu University, Faculty of Medicine, Fukuoka, Japan, and affiliated hospitals, from 1965 to 1984.

Measurements of DNA Content

Cell nuclear DNA analysis of the resected specimens was performed on 10-μ-thick paraffin sections stained according to Feulgen's method.[13] The DNA content was measured with a microspectrophotometer (MMSP, Olympus Co, Japan) and the two-wavelength method.[14] Data processing was carried out using a personal computer (HP-85, Hewlett-Packard Co) combined with a microspectrophotometer. In each section, 100 cancer cells were measured, and the relative DNA content in each cancer cell was determined. The mean DNA value of 25 stromal lymphocytes was used as the control of the normal diploid chromosome complement (2c). The DNA distribution pattern was divided into low and high groups, according to the frequency of aneuploid cell population.[15-17] A carcinoma with a population of over 10% of cells beyond the hexaploid (6c) range was designated as *high ploidy* (aneuploid carcinoma) and that without such a population was classed as *low ploidy*.

Classifications of Clinicopathologic Factors

Clinicopathologic factors, including depth of invasion, tumor size, gross type, location, nodal involvement, and prognosis, were reviewed in relation to individual DNA ploidy and to the two main types of gastric carcinoma (DT and UT), according to the classification of Sugano et al.[12] Gross type of tumor was grouped into types 0 to 5, according to the general rules outlined by the Japanese Research Society for gastric cancer.[18] Type 0 indicates

early carcinoma confined to the mucosa or the submucosa, regardless of the presence of lymph node metastasis, and includes elevated, flat, and depressed types. Advanced carcinoma, with invasion extending into the muscularis propria or beyond it, was classified into types 1 to 5. Types 1 to 4 correspond to Borrmann's classification,[18] and type 5 is one that cannot be classified under any of the above types in which early cancer–simulating advanced carcinomas are involved.

Statistical Analysis

Statistical analysis for tumor size was made using Student's *t* test; other statistical analyses were performed using the χ^2 test. Survival rate was estimated on the basis of the method of Kaplan and Meier.[19] Statistical analyses of the survival rate were carried out using the generalized Wilcoxon test. In the multivariate analysis, Cox' proportional hazard's model[20] was used to determine the prognostic significance of the various factors discussed.

Fig 1.—Frequency of aneuploid carcinoma according to depth of invasion classified as differentiated (at top) or undifferentiated (at bottom). Number in parentheses indicates number of cases. Asterisk indicates significant difference compared with mucosa (M) ($P<.01$) and compared with submucosa (SM) ($P<.01$). PM indicates muscularis propria; S, subserosa and serosa. Shaded bars represent high ploidy; open bars, low ploidy.

RESULTS

DNA Ploidy and Clinicopathologic Characteristics

Among the 254 patients were 102 (40.2%) cases of high ploidy, including 71 cases of the DT and 31 cases of the UT. Table 1 summarizes DNA ploidy and the clinicopathologic characteristics. There were statistically significant differences between low- and high-ploidy groups with regard to depth of invasion, histologic and gross types, tumor location, lymph node metastasis, curability in surgery, and the five-year survival rate. In cases of low ploidy, the carcinoma was confined to the mucosa, was UT in histologic type, was types 0 and 5 in gross appearance, involved the middle third of the stomach, showed no lymph node metastasis, and was resectable for potential cure. High ploidy was related to invasion into the serosal layer, was DT in histologic type, was types 2 and 3 in gross appearance, was located in the lower third of the stomach, showed nodal involvement, and was not resectable for potential cure. The five-year survival rate in the low-ploidy group was 90.6%, a value significantly higher than the five-year survival rate of 73.7% in the high-ploidy group ($P<.001$).

Frequency of Aneuploid Tumor Population According to Depth of Invasion

In DT cases, the rate of high ploidy was 42.9% at the mucosal stage and, at most, 68.4% at the serosal stage

*Number in parentheses indicates percentage.
†Significantly different from low ploidy ($P<.05$).

(Fig 1). There were no significant differences in the frequency of the aneuploid tumor population. Conversely, the UT was free of high-ploidy cases at the stage confined to the mucosa, while the frequency remarkably increased with progression of the tumor. The rate was 46.7% for serosal carcinoma. There were significant differences between events related to serosa and those related to the mucosa ($P<.01$) and between the serosa and the submucosa ($P<.01$).

DNA Ploidy and Tumor Size According to Depth of Invasion

Size of the tumors in each layer of the gastric wall is given in Table 2. The mean sizes were approximately equal in the layers of mucosa, submucosa, and muscularis propria, except in the case of UT classed as high ploidy. The size of the carcinoma invading the serosal layer was significantly larger than that of carcinoma limited to the muscularis propria ($P<.05$ in the low-ploidy group [DT] and $P<.01$ in the high-ploidy group [DT and UT]). Thus,

UT classed as high ploidy was dominant with regard to increases in tumor size, in proportion to invasion into the deeper layers.

DNA Ploidy and Gross Appearance

In the case of DT, the high-ploidy group frequently had elevated lesions at the early stage ($P<.01$), and type 2 lesions were the most common gross types of advanced carcinoma ($P<.05$) (Table 3). Conversely, depressed lesions of early carcinoma ($P<.01$) and type 5 lesions of advanced carcinoma ($P<.01$) were most commonly seen in the low-ploidy group. In cases of UT, gross appearance of an early carcinoma classed as high ploidy included one elevated lesion and two depressed lesions. On gross inspection of the advanced carcinoma, the high-ploidy cases were predominant in type 3 lesions ($P<.05$) and less frequent in type 5 lesions ($P<.01$). Advanced carcinoma classed as type 4 (the diffusely infiltrative type), most of which was histologically undifferentiated, belonged to the high-ploidy group as frequently as to the low-ploidy group. Characteristically, the carcinoma of type 4 involving the entire stomach was observed in four (44.4%) of nine cases of low ploidy and in seven (77.8%) of nine cases of high ploidy.

Metastatic Potential

The incidence of lymph node metastasis was higher in the high-ploidy group than in the low-ploidy group at the stage of invasion beyond the mucosa (Table 4). In case of DT, the difference in the incidence of nodal involvement was significant in cases of invasion confined to the submucosa and also in cases of invasion extending to the serosa in the high-ploidy group ($P<.05$). In cases of UT, a significant difference was evident only in carcinoma invading the serosa ($P<.05$). The DT classed as high ploidy had a lymph node metastasis even in cases of submucosal carcinoma, while in 18 of 21 with UT lesions and lymph node metastasis, the carcinoma had invaded the serosa.

Prognosis

There were four patients with an early carcinoma and a postoperative recurrence, including one with low ploidy and three with high ploidy. All four patients with a DT lesion had died five years after the operation. The ten-year survival rates of low- and high-ploidy groups with DT lesions were 94.4% and 88.4%, respectively (no statistically significant difference), while patients with UT lesions had a good clinical course regardless of the DNA ploidy. The postoperative survival curves for patients with advanced carcinoma are shown in Fig 2. The five-year survival rates of low- and high-ploidy groups were, respectively, 58.9% and 49.5% for patients with DT lesions and 77.5% and 37.5% for patients with UT lesions. In cases of UT, the difference was statistically significant ($P<.01$).

The relationship among mode of recurrence, postoperative survival time, and depth of invasion in the high-ploidy group is summarized in Fig 3. In 12 patients with DT lesions, the mucosa was invaded in two, the submucosa was invaded in one, the muscularis propria was invaded in two, and the serosa was invaded in seven. Of these patients, two with mucosal carcinoma died six years six months and nine years six months after operation with recurrences in the lung and liver, respectively. A patient with submucosal carcinoma died of multiple bone metastasis five years seven months after the operation. The mode of recurrence was confirmed in four of nine patients with advanced carcinoma. Liver metastasis occurred in three patients, including one with a lesion invading the muscularis propria and two with serosal carcinoma. Another patient with serosal invasion died of disseminating metastasis. Conversely, 16 of 17 with carcinoma classed as UT had a lesion extending to the serosa and died soon after operation. The mode of recurrence in 16 with serosal carcinoma included nine with disseminating metastasis, with or without liver metastasis, three with liver metastasis, one with a local recurrence in the remnant stomach, and three with an unknown pattern. Therefore, hematogenous metastasis usually occurred in patients with the DT carcinoma of aneuploidy, even when the invasion was confined to the mucosa or to the submucosa. Disseminating metastasis occurred more frequently in those with the UT carcinoma of aneuploidy extending to the serosa.

Multivariate Analysis of Prognostic Factors

A multivariate analysis was performed for 226 patients who underwent curative surgery. The variables analyzed included age, sex, tumor size, gross type, histologic types, depth of invasion, growth pattern, vessel invasion, lymphatic involvement, lymph node metastasis, extent of lymph node dissection, stage of disease, and DNA ploidy. Age of patients was classified into three types: under 49, 50 to 69, or over 70 years. Size of the tumor was also classified into three types: under 4.0, 4.1 to 8.0, or over 8.1 cm. Growth pattern was classified into the following three types: expansive, intermediate, or infiltrative. Vessel invasion and lymphatic involvement were classified into two categories: present or absent. Lymph node metastasis was classified into four categories: (1) no evidence of regional lymph node metastasis; (2) primary nodal involvement along the lesser or greater curvatures; (3) secondary nodal involvement, including that along the left gastric, splenic, celiac, and common hepatic arteries; or (4) tertiary nodal involvement, such as involvement of the hepatoduodenal, retropancreatic, and mesenteric nodes. The extent of lymph node dissection was classified into two categories: complete removal of the primary lymph node or complete removal of primary and secondary lymph nodes with or without dissection of tertiary nodes. Stage of the disease was classified into four types according to the histopathologic classification of the Japanese staging system.[18] Of these variables, DNA ploidy significantly influenced the prognosis ($P<.05$, $\chi^2=4.42$), as did the sex ($P<.01$, $\chi^2=7.27$), gross type ($P<.05$, $\chi^2=4.34$), vessel invasion, ($P<0.05$, $\chi^2=4.31$), extent of lymph node dissection ($P<.01$, $\chi^2=9.01$), and stage of disease ($P<0.01$, $\chi^2=6.90$).

COMMENT

There is general agreement that aneuploid tumors usually are related to an advanced disease. The involvement of surrounding tissues, metastasis, and a poor prognosis have been noted in cases of carcinoma of the colon,[1] esophagus,[2] and prostate.[3] In our study of gastric carcinoma, we noted an aneuploid carcinoma preponderance associated with lymph node metastasis, tumor invasion, and prognosis. The high-ploidy group had a greater population in the advanced stage than in the early stage and showed a stronger metastastic potential than the low-ploidy group,[15] resulting in a poorer prognosis.

We found a distinct difference in the mode of development between aneuploid tumors consisting of the DT and those of the UT. In the case of the DT with an abnormal DNA content, early carcinoma with an elevated form was frequent and often led to an advanced carcinoma of the ulcerating, circumscribed type (type 2). Conversely, in the case of the UT, the ulcerating infiltrative type (type 3) and diffusely infiltrative type (type 4) of advanced carcinoma

may occur, although little is known of the aneuploid tumor origin. Characteristically, the UT with an abnormal DNA content gave rise to a remarkable increase in frequency of aneuploid tumors, tumor size, and the metastatic potential during the progression from the early to the advanced stage. These findings are attributed to (1) a difference in growth rate between DT and UT or (2) a change in cytogenetic profile during the progression of the UT.

According to the DNA analysis, aneuploid carcinoma was present even in a lesion confined to the mucosa and less than 5 mm in diameter.[16] In such cases, there was a preponderance of the DT, and UT with an aneuploid profile was not included. The DNA characteristics did not change in the case of tumor progression into the gastric wall, as determined in a comparative study between primary and recurrent gastric carcinomas.[21] Hence, it is reasonable to consider that the UT featured by aneuploidy is rapid in growth and less likely to be detected until the advanced stage, thereby supporting the first hypothesis.

With regard to the second hypothesis, Hattori et al[22] reported that the diffuse type of carcinoma would be kinetically more heterogeneous than the intestinal type of carcinoma, because the former type showed differences in distribution of the tritiated thymidine–incorporated cells in the gastric wall. The cancer cells were not located in the superficial layer but rather were in the deeper layer. Haraguchi et al[17] obtained evidence of heterogeneous DNA ploidy in a small number (30%) of the UT of serosal carcinoma. In such cases, low-ploidy patterns were evident in the mucosal layer, and high-ploidy patterns were seen in some parts of the deeper layer. In light of these findings, a more malignant transformation may occur in a small number of cases during the progression of UT carcinoma of diploid origin from early to advanced stages.

In the multivariate analysis, DNA ploidy proved to be a major independent factor. In this respect, DNA analysis is useful for predicting the prognosis of patients who undergo curative surgery. We observed that the behavioristic features of aneuploid carcinoma are governed by the individual histologic types. A differentiated carcinoma with aneuploid profile was associated with nodal involvement and hematogenous metastasis, even at the early stage of disease. Conversely, the metastatic potential in the case of undifferentiated carcinoma was usually inhibited when the lesion was confined to the proper muscle layer. However, the prognosis was extremely poor when the carcinoma had invaded the serosa. Death seemed to relate to the occurrence of peritoneal dissemination. Well-planned treatment, including radical surgery, anticancer chemotherapy, and careful follow-up, will lead to more satisfactory results in treating patients with aneuploid gastric carcinoma.

This investigation was supported in part by the Grant-in-Aid for General Scientific Research 62480284 and for Encouragement of Young Scientists 63770990 from the Japanese Ministry of Education, Science, and Culture.

- ☐ No MTT side chain

MEFOXIN is indicated for the treatment of intraabdominal, gynecological, lower respiratory tract, and skin and skin-structure infections due to designated susceptible organisms including members of the *Bacteroides fragilis* group. (See Brief Summary for complete listing of indications.)

MEFOXIN is contraindicated in patients who have shown hypersensitivity to cefoxitin and the cephalosporin group of antibiotics. Before therapy with MEFOXIN is instituted, careful inquiry should be made to determine whether the patient has had previous hypersensitivity reactions to cefoxitin, cephalosporins, penicillins, or other drugs. This product should be given with caution to penicillin-sensitive patients.

Pseudomembranous colitis, from mild to life-threatening in severity, has been reported with virtually all antibiotics (including cephalosporins); therefore, it is important to consider its diagnosis when diarrhea develops in association with antibiotic use.

Mefoxin® IV/IM
(Cefoxitin Sodium | MSD)

*Percent susceptible at 16 mcg/mL: *B. fragilis* (91%), *B. thetaiotaomicron* (84%), *B. distasonis* (78%), *B. vulgatus* (88%), and *B. ovatus* (79%)—based on Antibiotic Susceptibility Reports, National Summary, in *The Bacteriologic Report: Volume I 1987*, Totowa, NJ, BAC-DATA® Medical Information Systems, Inc., 1987.

***In vitro* activity does not necessarily imply *in vivo* effectiveness.

For a Brief Summary of Prescribing Information, please see following page.

MSD
MERCK SHARP & DOHME

It's got to be Mefoxin® IV/IM

(Cefoxitin Sodium | MSD)

Indications and Usage: *Treatment*—Serious infections caused by susceptible strains of the designated microorganisms in the following diseases:
LOWER RESPIRATORY TRACT INFECTIONS, including pneumonia and lung abscess, caused by *Streptococcus pneumoniae*, other streptococci (excluding enterococci, e.g., *Strep. faecalis*), *Staphylococcus aureus* (penicillinase and non-penicillinase producing), *Escherichia coli*, *Klebsiella* species, *Hemophilus influenzae*, and *Bacteroides* species.
GENITOURINARY INFECTIONS. Urinary tract infections caused by *E. coli*, *Klebsiella* species, *Proteus mirabilis*, indole-positive *Proteus* (which include the organisms now called *Morganella morganii* and *Proteus vulgaris*), and *Providencia* species (including *Providencia rettgeri*). Uncomplicated gonorrhea due to *Neisseria gonorrhoeae* (penicillinase and non-penicillinase producing).
INTRA-ABDOMINAL INFECTIONS, including peritonitis and intra-abdominal abscess, caused by *E. coli*, *Klebsiella* species, *Bacteroides* species including the *B. fragilis* group,* and *Clostridium* species.
GYNECOLOGICAL INFECTIONS, including endometritis, pelvic cellulitis, and pelvic inflammatory disease, caused by *E. coli*, *N. gonorrhoeae* (penicillinase and non-penicillinase producing), *Bacteroides* species including the *B. fragilis* group,* *Clostridium* species, *Peptococcus* species, *Peptostreptococcus* species, and group B streptococci.
SEPTICEMIA caused by *Strep. pneumoniae*, *Staph. aureus* (penicillinase and non-penicillinase producing), *E. coli*, *Klebsiella* species, and *Bacteroides* species including the *B. fragilis* group.*
BONE AND JOINT INFECTIONS caused by *Staph. aureus* (penicillinase and non-penicillinase producing).
SKIN AND SKIN STRUCTURE INFECTIONS caused by *Staph. aureus* (penicillinase and non-penicillinase producing), *Staph. epidermidis*, streptococci (excluding enterococci, e.g., *Strep. faecalis*), *E. coli*, *P. mirabilis*, *Klebsiella* species, *Bacteroides* species including the *B. fragilis* group,* *Clostridium* species, *Peptococcus* species, and *Peptostreptococcus* species.
Although appropriate culture and susceptibility studies should be performed, therapy may be started while awaiting these results. Cefoxitin is not active *in vitro* against most strains of *Pseudomonas aeruginosa* and enterococci (e.g., *Strep. faecalis*) and many strains of *Enterobacter cloacae*. Methicillin-resistant staphylococci are almost uniformly resistant to cefoxitin.
Prevention—Prophylactic use in surgical procedures (e.g., hysterectomy, gastrointestinal surgery, cesarean section, transurethral prostatectomy) classified as contaminated or potentially contaminated or in patients in whom subsequent infection at the operative site would present a serious risk, e.g., prosthetic arthroplasty.
MEFOXIN® (Cefoxitin Sodium, MSD) usually should be given ½ to 1 hour before surgery and should usually be stopped within 24 hours since continuing administration of any antibiotic increases the possibility of adverse reactions but, in the majority of surgical procedures, does not reduce the incidence of subsequent infection. However, in patients undergoing prosthetic arthroplasty, it is recommended that MEFOXIN be continued for 72 hours after the surgical procedure. If there are signs of infection, specimens for culture should be obtained for identification of the causative organism so appropriate treatment may be instituted.

Contraindications: Previous hypersensitivity to cefoxitin and the cephalosporin group of antibiotics.

Warnings: BEFORE THERAPY IS INSTITUTED, CAREFUL INQUIRY SHOULD BE MADE TO DETERMINE PREVIOUS HYPERSENSITIVITY REACTIONS TO CEFOXITIN, CEPHALOSPORINS, PENICILLINS, OR OTHER DRUGS. GIVE WITH CAUTION TO PENICILLIN-SENSITIVE PATIENTS. ANTIBIOTICS SHOULD BE ADMINISTERED WITH CAUTION TO ANY PATIENT WHO HAS DEMONSTRATED SOME FORM OF ALLERGY, PARTICULARLY TO DRUGS. IF AN ALLERGIC REACTION TO CEFOXITIN OCCURS, DISCONTINUE THE DRUG. SERIOUS HYPERSENSITIVITY REACTIONS MAY REQUIRE EPINEPHRINE AND OTHER EMERGENCY MEASURES.
Pseudomembranous colitis, from mild to life-threatening in severity, has been reported with virtually all antibiotics (including cephalosporins); therefore, it is important to consider its diagnosis when diarrhea develops in association with antibiotic use. Broad-spectrum antibiotics alter normal flora of colon and may permit overgrowth of clostridia; a toxin produced by *Clostridium difficile* is a primary cause of antibiotic-associated colitis. Mild cases may respond to drug discontinuance alone; in more severe cases, management may include sigmoidoscopy, appropriate bacteriological studies, fluid, electrolyte and protein supplementation, and use of a drug such as oral vancomycin; isolation of the patient may be advisable. Other causes of colitis should also be considered.

Precautions: *General*—Total daily dose should be reduced in patients with reduced urinary output due to renal insufficiency because high and prolonged serum antibiotic concentrations can occur from usual doses. Prescribe with caution in patients with a history of gastrointestinal disease, particularly colitis. Prolonged use may result in overgrowth of nonsusceptible organisms; repeated evaluation of the patient's condition is essential. If superinfection occurs, take appropriate measures.
Drug Interactions—Increased nephrotoxicity has been reported following concomitant administration of cephalosporins and aminoglycoside antibiotics.
Drug/Laboratory Test Interactions—High concentrations (>100 mcg/mL) may interfere with measurement of serum and urine creatinine levels by the Jaffé reaction and produce false increases of modest degree in creatinine levels reported; serum samples should not be analyzed for creatinine if withdrawn within 2 hours of cefoxitin administration. High concentrations may interfere with measurement of urinary 17-hydroxy-corticosteroids by the Porter-Silber reaction and produce false increases of modest degree in levels reported. A false-positive reaction for glucose in urine has been observed with CLINITEST** reagent tablets.
Carcinogenesis, Mutagenesis, Fertility Impairment—No long-term animal study has been performed on carcinogenic or mutagenic potential. Rat studies at approximately three times maximum recommended human dosage revealed no effects on fertility or mating ability.
Pregnancy Category B—Reproduction studies in rats and mice did not reveal teratogenic or fetal toxic effects, although fetal weights were slightly decreased. In rabbits, cefoxitin was associated with a high incidence of abortion and maternal death, neither considered teratogenic. There are, however, no adequate and well-controlled studies in pregnant women. Because animal reproduction studies are not always predictive of human response, this drug should be used during pregnancy only if clearly needed.
Nursing Mothers—Excreted in human milk: Exercise caution.
Pediatric Use—Safety and efficacy in infants from birth to three months have not yet been established. In children three months and older, higher doses have been associated with increased incidence of eosinophilia and elevated SGOT.

Adverse Reactions: The most common adverse reactions have been local reactions following intravenous or intramuscular injection. Other adverse reactions have been encountered infrequently. *Local Reactions*—Thrombophlebitis with intravenous administration; pain, induration, and tenderness after intramuscular injections. *Allergic Reactions*—Rash (including exfoliative dermatitis), pruritus, eosinophilia, fever, and other allergic reactions including anaphylaxis. *Cardiovascular*—Hypotension.
Gastrointestinal—Diarrhea, including documented pseudomembranous colitis during or after treatment, and, rarely, nausea and vomiting. *Blood*—Eosinophilia, leukopenia including granulocytopenia, neutropenia, anemia, including hemolytic anemia, thrombocytopenia, and bone marrow depression. A positive direct Coombs test may develop in some individuals, especially those with azotemia. *Liver Function*—Transient elevations in SGOT, SGPT, serum LDH, and serum alkaline phosphatase; jaundice. *Renal Function*—Elevations in serum creatinine and/or blood urea nitrogen levels and, rarely, acute renal failure.

Note: In group A beta-hemolytic streptococcal infections, therapy should be maintained for at least 10 days to guard against the risk of rheumatic fever or glomerulonephritis. In staphylococcal and other infections involving a collection of pus, surgical drainage should be carried out where indicated. Intramuscular injections should be well within the body of a relatively large muscle such as the upper outer quadrant of the buttock (i.e., gluteus maximus); aspiration is necessary to avoid inadvertent injection into a blood vessel. The total daily dosage in infants and children should not exceed 12 grams.

How Supplied: Sterile cefoxitin sodium in vials, infusion bottles, and ADD-Vantage®† vials containing 1 gram or 2 grams cefoxitin equivalent and in 10-gram bulk bottles.

* *B. fragilis*, *B. distasonis*, *B. ovatus*, *B. thetaiotaomicron*, *B. vulgatus*

Prophylactic Antibiotherapy in Abdominal Surgery

First- vs Third-Generation Cephalosporins

Nelly Rotman, MD; Jean-Marie Hay, MD; François Lacaine, MD;
Pierre-Louis Fagniez, MD; the Association de Recherche en Chirurgie Cooperative Group

• To compare the efficiency of antibioprophylaxis by cefazolin sodium or cefotaxime sodium, 3137 consecutive patients undergoing abdominal surgery were included in a prospective, randomized, controlled, multicenter study. The patients were divided into four strata, according to the degree of contamination during the operation and the risk factors. Within each stratum, the patients were randomized into three groups of treatment: (1) cefazolin, (2) cefotaxime, and (3) nontreatment (control). Antibiotics were administered perioperatively in three intravenous doses of 1 g at eight-hour intervals. Patients undergoing colon surgery or with peritonitis at the time of the operation were excluded from the study. The wound abscess rate was significantly lower in the treated groups than in the control group, except in stratum 3 (contaminated surgery). The percentage of postoperative peritonitis was twice as low in the treated groups as in the control group. There was no difference between the groups receiving cefazolin or cefotaxime. The patients in the treated groups received significantly less postoperative antibiotics than the patients in the control group. In terms of cost, antibioprophylaxis by cefazolin seems to be warranted in all operations with a low anaerobic contamination.

(*Arch Surg* 1989;124:323-327)

In the last two decades, several studies have demonstrated the benefits offered by prophylactic antibiotherapy in some surgical settings, and these studies have helped to clarify the type, timing, and duration of antimicrobial prophylaxis.[1-4] The efficiency of prophylactic antibiotherapy is well established for gynecologic and high-risk biliary and gastric surgery, as well as for colorectal surgery.[3] However, controversy remains concerning the usefulness of antibioprophylaxis in surgical procedures with spontaneous, minimal postoperative infection.[5] Another question concerns the choice of the more appropriate prophylactic antibiotic, which has been complicated since third-generation cephalosporins have become available. Because of their broad-spectrum effectiveness against the digestive tract pathogens and their minimal adverse effects, cephalosporins are commonly administered for prophylaxis in patients undergoing surgery. In a prospective evaluation of antimicrobial prophylaxis, Crossley et al[6] showed that more than half of the patients received a cephalosporin. Although second- and third-generation cephalosporins have an expanded spectrum, their superiority over first-generation cephalosporins for surgical prophylaxis has not been demonstrated.[7-10] The aim of this study on 3137 consecutive patients undergoing abdominal surgery was to evaluate the benefits of prophylactic antibiotherapy by comparing treated and untreated patients and to compare the efficiency of a first-generation (cefazolin) and a third-generation (cefotaxime sodium) cephalosporin in preventing postoperative infection.

PATIENTS AND METHODS

During a four-year period (June 1982 through June 1986), 3137 consecutive patients were included in a prospective, randomized, controlled, multicenter study.

Patient Selection

All patients undergoing intra-abdominal or parietoabdominal surgery were included in the study. The patients were divided into three strata, according to the degree of contamination of the operation. This distribution was made according to the classification of the National Research Council.[11] Stratum 1 included operative procedures in which neither the digestive nor the genitourinary tracts were entered (clean). Stratum 2 included the operations with a low contamination (clean-contaminated), and stratum 3 included operative procedures in which more endogenous organisms were likely to be encountered (contaminated). A fourth stratum was designed to include patients with a high risk of infection whatever the operation. The classification of patients according to surgical procedure was as follows:

Stratum 1
- Abdominal and groin hernia (elective procedures)
- Hiatal hernia
- Hyperselective vagotomy
- Staging, exploratory laparotomy
- Vascular surgery
- Ovarian cyst

Stratum 2
- Cholecystectomy
- Elective gastrectomy (cancer and/or stenosis excluded)
- Hepatectomy
- Pancreatectomy (acute pancreatitis excluded)
- Hysterectomy

Stratum 3
- Small-bowel obstruction
- Small-bowel resection
- Common bile duct surgery
- Appendectomy
- Gastrectomy (cancer and/or stenosis)

Stratum 4
- Diabetes mellitus
- Ascites
- Obesity (>20%)
- Weight loss (>15%)
- Abdominal radiotherapy
- Steroids } within 6 mo before surgery
- Chemotherapy }

Excluded preoperatively from the study were (1) patients who had received antimicrobial therapy within 15 days before surgery, (2) patients with a known allergy to cephalosporins or renal failure, and (3) patients undergoing colon surgery. These latter patients were excluded because their allocation in a nontreatment group is unethical.[12]

Only patients undergoing vascular procedures without prosthetic material were included in the study. The patients with peritonitis or intra-abdominal abscesses, discovered at the time of operation, were given curative antibiotherapy and thus were withdrawn from the study. The patients who received postoperative curative antibiotherapy for a postoperative intra-abdominal or extra-abdominal infection were not excluded from the study.

The age, sex, type of surgical procedure, length of operation, and duration of hospital stay were recorded for each patient.

Methods

Patients were given either cefazolin, cefotaxime (treated groups), or no antibiotherapy (control group). The allocation to one of the three groups was performed by a computer-generated randomization. The random assignment was balanced within each center. A form was filled out for each patient. The type of treatment to be performed was concealed in the upper-right-hand corner of the form that was unsealed by the anesthetist in the operating room. This method was preferred to that of sealed envelopes, to avoid nonsequential allocation when the order of the envelopes became mixed.[13] Each drug was administered intravenously in three doses for a total dose of 3 g. The first dose was given 20 minutes before the anesthetic induction. The subsequent doses were administered at eight-hour intervals.

Skin preparation was done in the operating room, using either povidone-iodine (Betadine) or tincture of chlorhexidine gluconate (Hibitane). Local irrigation of the wound and/or the peritoneal cavity was performed in all the cases with the antiseptic used for skin preparation.

The study was approved by the Comité d'Ethique of the Paris XII University.

Criteria for Evaluation of Efficiency of Prophylactic Antibiotherapy

Failure of prophylactic antibiotherapy was defined as the occurrence of an infection at the operative site. Patients were examined daily during their hospital stay by a physician unaware of the prophylactic antimicrobial regimen. All the patients underwent a physical examination 30 to 40 days after they were discharged from the hospital, in order not to overlook a late wound abscess. The main criterion for the evaluation of prophylactic antibiotherapy was the presence of a wound abscess at the site of operation. A wound abscess was defined on clinical grounds as a purulent exudate. The occurrences of intra-abdominal or extra-abdominal infectious complications (pulmonary infection, urinary tract infection, or septicemia), as well as noninfectious complications (myocardial infarction, phlebitis, pulmonary embolism, liver failure, or neurologic disorders), were also recorded.

Statistical Analysis

The number of patients necessary for the study was defined so as to obtain a reduction in the wound abscess rate from 7% (with no antibiotherapy) to 3.5% (with antibiotherapy), with a type I error of 0.05 and a type II error of 0.05. The estimation of the wound abscess rate was made according to the study of the Ad Hoc Committee on Trauma.[14] The calculated number of patients necessary for the study was 1015 in each group (two-sided test). The χ^2 and Student's t tests were used to compare the characteristics of the three groups.[15]

RESULTS

After randomization, the following were withdrawn from the study: 187 patients with an intra-abdominal abscess or peritonitis at the time of operation, 17 patients who had received preoperative antibiotherapy, and 19 patients with an inadequate prophylactic regimen.

Clinical data and follow-up were available in 3137 patients. The clinical data of the patients are listed in Table 1. The number of operations on the digestive tract, the length of operation, and the duration of the hospital stay were not different among the three groups within each stratum. In stratum 4, there were significantly more men, and the patients were significantly younger in the control than in the treated groups. In stratum 3, there were significantly more women in the control than in the cefotaxime-treated group.

The number of patients undergoing skin preparation with povidone-iodine or chlorhexidine was not different in each group of treatment, except in stratum 3 of the cefotaxime-treated group, in which significantly more patients had skin preparation with chlorhexidine (Table 2).

Postoperative Complications

In stratum 4, independent of the treatment group, the rate of infectious and noninfectious complications, as well as the mortality, were significantly higher ($P<.001$) than in strata 1, 2, and 3 (Table 3).

Parietal Infection

The incidence of wound abscesses was significantly lower in the groups receiving prophylactic antibiotherapy than in the control group ($P<.001$) (Table 4). When analysis was carried out separately in each stratum, antibioprophylaxis was effective in clean operations, with a decrease in the

*No statistical difference has been found, unless specified.

wound abscess rate from 4% in the untreated group to 0.4% in the treated groups. Similar results were found in strata 2 and 4. In stratum 3, there was no statistically significant difference between the treated and untreated groups, although the percentage of wound abscesses was lower in the treated groups. There was no statistically significant difference for wound abscess between the groups receiving cefazolin or cefotaxime.

Intra-abdominal Infectious Complications

The percentage of postoperative intra-abdominal infection (generalized or localized peritonitis) was twice as low in the groups receiving prophylactic antibiotics as in the control group. However, this result was statistically significant only in the cefotaxime-treated group. There was no statistical difference between the groups receiving cefazolin or cefotaxime (Table 5).

Extra-abdominal Infectious Complications

The rate of urinary tract infection was significantly lower in the cefotaxime-treated groups ($P<.02$) as compared with the cefazolin-treated group (Table 5). There was no significant difference between the control group and the treated groups.

The postoperative pulmonary infection rate was significantly lower in the group receiving cefazolin than in the control and cefotaxime-treated groups ($P<.05$). The number of septicemias was not different in the three groups.

Three hundred sixty-six patients (11.6%) were given postoperative curative antibiotherapy for an extra-abdominal or intra-abdominal infection. The patients treated by prophylactic antibiotics required significantly less postoperative antibiotherapy than the patients in the control group. There was no statistically significant difference between the groups receiving cefazolin or cefotaxime. There was no statistically significant difference between the three groups of treatment concerning the mortality. *Noninfectious complications* were not different in the three groups (Table 5).

COMMENT

Numerous studies have been carried out on antibioprophylaxis in patients undergoing surgery, but in most of them, the number of patients is too low for the study to be

conclusive.[16] This prospective, randomized, controlled, multicenter study on prophylactic antibiotherapy in abdominal surgery was undertaken to evaluate the actual efficiency of cephalosporins in preventing postoperative infectious complications and to compare first- and third-generation cephalosporins on a sufficient number of patients.

Cephalosporins were selected as the antimicrobial agent because this class of antibiotics is effective against potentially pathogenic microorganisms encountered in abdominal surgery, ie, gram-positive cocci and gram-negative aerobes. The mode of administration of prophylactic antibiotherapy used in the present study relied on well-established principles: there is no need to give antibiotics before the induction of anesthesia,[17,18] and a prolonged course of treatment offers no advantages compared with a 24-hour course.[3,4]

The surgical procedures were graded in clean, clean-contaminated, and contaminated operations. We thought it was necessary to create another stratum for "at-risk" patients, whatever the type of operation. Age, diabetes, obesity, and malnutrition increase the wound abscess rate.[18,19] This stratum was individualized to obtain an even distribution of at-risk patients in each of the treatment groups, as recommended by Solomkin et al.[20] The rate of postoperative complications (infectious and noninfectious) was significantly higher in stratum 4 compared with the other strata. This result highlights the importance of the host condition in the occurrence of postoperative complications. Within each stratum, the three groups of treatment were not significantly different with regard to the type and length of the operation and the hospital stay. The extended hospital stay in stratum 1 may result from the duration of preoperative hospitalization, with most of the preoperative investigations being performed in the hospital.

A wound abscess was chosen as the main criterion for the evaluation of antibioprophylaxis, because the occurrence of a wound abscess is usually said to be responsible for an extended hospital stay and an increase in the overall costs. The patients were followed up for at least 30 days after their discharge from the hospital to avoid overlooking a late wound abscess that could have been delayed by the use of prophylactic antibiotherapy and could have resulted in a bias in the study. The results of the study demonstrate that a first-generation cephalosporin (cefazolin) is as effective as a third-generation cephalosporin (cefotaxime) in decreasing the overall wound abscess rate, when compared with the untreated group of patients. This is in accordance with the results of the randomized trial by Jones et al,[10] who compared antibioprophylaxis with cefazolin and cefotaxime in various elective surgical procedures.

When analysis is carried out separately in each stratum, antibioprophylaxis is effective in decreasing the wound abscess rate in clean operations. Similar results are found in clean-contaminated (stratum 2) and at-risk (stratum 4) groups. In the contaminated group (stratum 3), there was no statistically significant difference between the treated and untreated groups, although the wound abscess rate was lower in the treated groups. This can be explained by the fact that stratum 3 included bowel resection and appendectomy, with both operations being contaminated

by a more important proportion of anaerobes against which the cephalosporins used in the study have a modest activity.[7] If prophylactic antibiotherapy is considered for these types of operations, another antibiotic regimen should be used.[21] Antibioprophylaxis in clean surgery is strongly questioned, because the postoperative infection rate is spontaneously low and can be lowered by simple skin preparation.[18,22] In clean surgical cases, prophylactic antibiotherapy can be of benefit if the cost of antibiotics is lower than the cost of treatment of a wound abscess. In our study, there was no difference in the hospital stay of the patients, whether they received prophylactic antibiotics or not, with all the wound abscesses being treated at the outpatient department. The cost of an eight-day treatment of a wound abscess, with two dressings per day by a specialized nurse, amounts to $217. The overall cost of wound abscess treatment in the control group (57 wound abscesses for 1060 patients) amounts to approximately $12 400. The cost of prophylaxis with cefotaxime sodium in 1049 patients, with a 3-g regimen, amounts to $21 075. When the cost of treatment of the wound abscesses that occurred in this group is added up, the total cost reaches $26 000. When the same calculation is made for prophylaxis by cefazolin, the total cost is $9200. Furthermore, the patients in the control groups received significantly more postoperative antibiotherapy compared with the patients given cefazolin or cefotaxime perioperatively. The cost of postoperative antibiotherapy cannot be evaluated from the data collected in this study, but it is not unlikely that some benefit in cost can be obtained by a 24-hour course of cefazolin, even in the clean-surgery group.

The number of cases of localized or generalized postoperative peritonitis was lower in the groups receiving prophylaxis than in the control group. This is in accordance with previous reports that have shown a beneficial effect of antibioprophylaxis on postoperative intra-abdominal sepsis.[2,12] Nevertheless, although the postoperative peritonitis rate in the cefazolin- and cefotaxime-treated groups was half that of the control group, this result is statistically significant only for cefotaxime. This result must be interpreted cautiously, as statistical significance would be reached for the cefazolin-treated group with only one more patient. For this reason, the superiority of cefotaxime over cefazolin in preventing postoperative intra-abdominal sepsis is not likely.

Antibioprophylaxis has a less clear-cut effect on extra-abdominal infectious complications. The type of organisms responsible for the pulmonary and urinary tract infections are not available for all the patients, and their susceptibility to the antibiotics used for prophylaxis cannot be assessed. In our series, the mortality is similar in the three groups. This result may be related to the exclusion of patients undergoing colon surgery, for which it is well established that antibioprophylaxis decreases the mortality.[12] Up to now, there has been no evidence of the superiority of third-generation over first-generation cephalosporins.[7-10] The results of our study confirm this finding: cefazolin is as effective as cefotaxime in decreasing the postoperative wound abscess rate, and both prophylactic regimens decrease the rate of postoperative peritonitis. The present study was started in 1982 at a time when the duration of antibioprophylaxis exceeded 48 hours,[6] and its results have confirmed that a 24-hour course of antibiotics is sufficient to decrease the postoperative wound infection rate. Since our study, recent investigations have shown that a single-dose prophylactic regimen, using newer antimicrobial agents, could be all that is necessary for the prevention of wound abscesses.[10] Nevertheless, more studies on large groups of patients are required to establish the best single-dose prophylactic regimen. For this reason, in 1987, we started a study comparing a one-dose prophylaxis with ceftriaxone vs a three-dose regimen with cefazolin.

CONTROL THE ACID RISK

Unlike antacids or sucralfate, ZANTAC® Injection controls both gastric pH and gastric volume. ZANTAC 50 mg IV rapidly increases pH to 6.2 within 1½ hours and keeps it within a desirable range for up to 8 hours.[1] And ZANTAC reduces secretory volume—up to 50% after administration of a 50 mg intravenous dose.[2]

ZANTAC 50 mg IV q6-8h instead of antacids—to help reduce the risk of aspiration pneumonitis, diarrhea, or alkalosis.

- ZANTAC produces no clinically significant drug interactions with theophylline, phenytoin, or warfarin.
- ZANTAC does not affect blood levels of medications metabolized by the hepatic cytochrome P-450 enzyme system, such as propranolol, diazepam, lidocaine, meperidine, carbamazepine, or valproic acid.

Zantac® Injection

ranitidine HCl/Glaxo 25 mg/ml

2 ml single-dose vials
10 ml multi-dose vials
40 ml Pharmacy Bulk Packages
2 ml single-dose, prefilled, disposable syringes

Injection Premixed 50 mg/100 ml

Glaxo/ ROCHE

ZANTAC® Injection
(ranitidine hydrochloride)

BRIEF SUMMARY

ZANTAC® Injection Premixed
(ranitidine hydrochloride)

The following is a brief summary only. Before prescribing, see complete prescribing information in ZANTAC® Injection/ZANTAC® Injection Premixed product labeling.

INDICATIONS AND USAGE: ZANTAC® Injection and ZANTAC® Injection Premixed are indicated in some hospitalized patients with pathological hypersecretory conditions or intractable duodenal ulcers, or as an alternative to the oral dosage form for short-term use in patients who are unable to take oral medication.

CONTRAINDICATIONS: ZANTAC® Injection and ZANTAC® Injection Premixed are contraindicated for patients known to have hypersensitivity to the drug.

PRECAUTIONS: General: 1. Symptomatic response to ZANTAC® therapy does not preclude the presence of gastric malignancy.
2. Since ZANTAC is excreted primarily by the kidney, dosage should be adjusted in patients with impaired renal function (see DOSAGE AND ADMINISTRATION). Caution should be observed in patients with hepatic dysfunction since ZANTAC is metabolized in the liver.
3. In controlled studies in normal volunteers, elevations in SGPT have been observed when H_2-antagonists have been administered intravenously at greater than recommended doses for five days or longer. Therefore, it seems prudent in patients receiving IV ranitidine at doses greater than or equal to 100 mg qid for periods of five days or longer to monitor SGPT daily (from day 5) for the remainder of IV therapy.
4. Bradycardia in association with rapid administration of ZANTAC Injection has been reported rarely, usually in patients with factors predisposing to cardiac rhythm disturbances. Recommended rates of administration should not be exceeded (see DOSAGE AND ADMINISTRATION).

Laboratory Tests: False-positive tests for urine protein with Multistix® may occur during ZANTAC therapy, and therefore testing with sulfosalicylic acid is recommended.

Drug Interactions: Although ZANTAC has been reported to bind weakly to cytochrome P-450 in vitro, recommended doses of the drug do not inhibit the action of the cytochrome P-450-linked oxygenase enzymes in the liver. However, there have been isolated reports of drug interactions that suggest that ZANTAC may affect the bioavailability of certain drugs by some mechanism as yet unidentified (eg, a pH-dependent effect on absorption or a change in volume of distribution).

Carcinogenesis, Mutagenesis, Impairment of Fertility: There was no indication of tumorigenic or carcinogenic effects in lifespan studies in mice and rats at oral doses up to 2,000 mg/kg/day.

Ranitidine was not mutagenic in standard bacterial tests (*Salmonella, Escherichia coli*) for mutagenicity at concentrations up to the maximum recommended for these assays.

In a dominant lethal assay, a single oral dose of 1,000 mg/kg to male rats was without effect on the outcome of two matings per week for the next nine weeks.

Pregnancy: *Teratogenic Effects: Pregnancy Category B*: Reproduction studies have been performed in rats and rabbits at oral doses up to 160 times the human oral dose and have revealed no evidence of impaired fertility or harm to the fetus due to ZANTAC. There are, however, no adequate and well-controlled studies in pregnant women. Because animal reproduction studies are not always predictive of human response, this drug should be used during pregnancy only if clearly needed.

Nursing Mothers: ZANTAC is secreted in human milk. Caution should be exercised when ZANTAC is administered to a nursing mother.

Pediatric Use: Safety and effectiveness in children have not been established.

Use in Elderly Patients: Ulcer healing rates in elderly patients (65 to 82 years of age) treated with oral ZANTAC were no different from those in younger age groups. The incidence rates for adverse events and laboratory abnormalities were also not different from those seen in other age groups.

ADVERSE REACTIONS: Transient pain at the site of intramuscular injection has been reported. Transient local burning or itching has been reported with intravenous administration of ZANTAC®.

The following have been reported as events in clinical trials or in the routine management of patients treated with oral or parenteral ZANTAC. The relationship to ZANTAC therapy has been unclear in many cases. Headache, sometimes severe, seems to be related to ZANTAC administration.

Central Nervous System: Rarely, malaise, dizziness, somnolence, insomnia, and vertigo. Rare cases of reversible mental confusion, agitation, depression, and hallucinations have been reported, predominantly in severely ill elderly patients. Rare cases of reversible blurred vision suggestive of a change in accommodation have been reported.

Cardiovascular: As with other H_2-blockers, rare reports of arrhythmias such as tachycardia, bradycardia, asystole, A-V block, and premature ventricular beats.

Gastrointestinal: Constipation, diarrhea, nausea/vomiting, abdominal discomfort/pain, and rare reports of pancreatitis.

Hepatic: In normal volunteers, SGPT values were increased to at least twice the pretreatment levels in 6 of 12 subjects receiving 100 mg qid IV for seven days, and in 4 of 24 subjects receiving 50 mg qid IV for five days. With oral administration there have been occasional reports of hepatitis, hepatocellular or hepatocanalicular or mixed, with or without jaundice. These were usually reversible.

Musculoskeletal: Rare reports of arthralgias.

Hematologic: Reversible blood count changes (leukopenia, granulocytopenia, and thrombocytopenia) have occurred in a few patients. Rare cases of agranulocytosis, pancytopenia, sometimes with marrow hypoplasia, and aplastic anemia have been reported.

Endocrine: Controlled studies in animals and man have shown no stimulation of any pituitary hormone by ZANTAC and no antiandrogenic activity, and cimetidine-induced gynecomastia and impotence in hypersecretory patients have resolved when ZANTAC has been substituted. However, occasional cases of gynecomastia, impotence, and loss of libido have been reported in male patients receiving ZANTAC, but the incidence did not differ from that in the general population.

Integumentary: Rash, including rare cases suggestive of mild erythema multiforme, and, rarely, alopecia.

Other: Rare cases of hypersensitivity reactions (eg, bronchospasm, fever, rash, eosinophilia), anaphylaxis, angioneurotic edema, and small increases in serum creatinine.

OVERDOSAGE: Information concerning possible overdosage and its treatment appears in the full prescribing information.

DOSAGE AND ADMINISTRATION: (See complete prescribing information in ZANTAC® Injection/ZANTAC® Injection Premixed product labeling.)

Dosage Adjustment for Patients with Impaired Renal Function: On the basis of experience with a group of subjects with severely impaired renal function treated with ZANTAC, the recommended dosage in patients with a creatinine clearance less than 50 ml/min is 50 mg every 18 to 24 hours. Should the patient's condition require, the frequency of dosing may be increased to every 12 hours or even further with caution. Hemodialysis reduces the level of circulating ranitidine. Ideally, the dosage schedule should be adjusted so that the timing of a scheduled dose coincides with the end of hemodialysis.

HOW SUPPLIED: ZANTAC® Injection, 25 mg/ml, containing phenol 0.5% as preservative, is available as follows:
NDC 0173-0362-38 2-ml single-dose vials (Tray of 10)
NDC 0173-0363-39 10-ml multi-dose vials (Singles)
NDC 0173-0363-00 40-ml Pharmacy Bulk Packages (Singles)
NDC 0173-0362-00 2-ml single-dose, prefilled, disposable syringes (Singles)

Store below 30°C (86°F). Protect from light.

ZANTAC Injection Premixed in 0.45% Sodium Chloride, 0.5 mg/ml, is available as a sterile premixed solution for IV administration in 100-ml single-dose flexible plastic containers (NDC 0173-0407-00). It contains no preservatives.

Exposure of pharmaceutical products to heat should be minimized. Avoid excessive heat. Protect from freezing. It is recommended that the product be stored at room temperature (25°C); however, brief exposure up to 40°C does not adversely affect the product.

Guidelines for Practical Utilization of Intraoperative Frozen Sections

Marianne U. Prey, MD; Thomas Vitale, MD; Scott A. Martin, MD

• We reviewed 4057 intraoperative frozen sections from 1980 through 1984 to assess the accuracy, strengths, and weaknesses of this technique. Breast, lymph node, and skin comprised half of the sites evaluated. Frozen-section and final diagnoses agreed in 91.5% and disagreed in 6.8% of the cases; 1.7% of the cases were deferred. False-negative frozen-section diagnoses were due to pathologist sampling or judgment errors and surgeon sampling errors. There were eight (0.15%) false-positive diagnoses, none of which altered patient treatment. We recommend that lymph nodes for lymphoproliferative disorders and breast tissue for which a malignant diagnosis will not result in an immediate mastectomy not be submitted for frozen-section diagnosis. Appropriate studies of these tissues can be carried out without an intraoperative diagnosis; such a policy will increase the cost-effectiveness of frozen sections without compromising patient care.

(*Arch Surg* 1989;124:331-335)

The technique of freezing tissue to cut slices thin enough to be interpreted by light microscopy has been used for over 100 years.[1] Technological advances have simplified the process, making the frozen section rapid interpretation a readily available procedure. This ease, however, should not justify the performance of the procedure. From numerous reports of frozen-section data in the literature, it is widely asserted that the only reasonable request for an intraoperative frozen section is to obtain a diagnosis that will direct the course of surgery or affect immediate (within 24 hours) postoperative patient care.[2-5] Notwithstanding these reports, it is our opinion that some frozen sections continue to be requested even when the results will not influence the immediate management of the patient.

The purpose of this study was twofold. First, we assessed the accuracy of frozen-section diagnoses and identified strengths and weaknesses with this technique. Second, we analyzed the patterns of frozen-section utilization by tissue site to establish practical guidelines for the use of the intraoperative frozen section.

Accepted for publication Dec 18, 1987.

From the Departments of Pathology, St Louis University (Dr Prey) and St John's Mercy Medical Center (Drs Prey and Martin), St Louis; and the Department of Surgery, Holmes Regional Medical Center, Melbourne, Fla (Dr Vitale). Dr Prey is now with SmithKlein Bio-Science Laboratories, St Louis.

Reprints not available.

As additional ancillary techniques for tissue study become more numerous and complex, the allocation and handling of specimens by the pathologist for diagnostic procedures is critical. It is necessary, therefore, that the pathologist and the surgeon be fully aware of the limitations of intraoperative frozen sections so that the procedure is used only judiciously and that specimens are not wasted, particularly when they are of limited size or volume.

MATERIALS AND METHODS

Surgical pathology accessions at St John's Mercy Medical Center, St Louis, that included intraoperative frozen-section consultations during a five-year period from 1980 through 1984 were reviewed. The final pathology reports from 4057 cases provided the database for this report. Frozen-section diagnoses that were stated in the reports were classified as benign, malignant, or deferred and were then compared with the final diagnoses in the reports. Actual histologic sections were not reviewed, since one of the objectives of the study was to assess the accuracy of our reported intraoperative frozen-section diagnoses. An audit of the accuracy of our final diagnoses was not an objective. In the absence of a deferral, the intraoperative diagnosis either agreed or disagreed with the final diagnosis. When there was disagreement, the reviewers (M.U.P. and S.A.M.) classified the frozen-section diagnosis as false positive, false negative, or other diagnostic discrepancy.

Designation of a false-positive result required an erroneous malignant frozen-section diagnosis and a benign final interpretation of the same specimen. Designation of a false-negative result required an erroneous benign frozen-section diagnosis and a malignant final diagnosis. The "other" category was employed when the frozen-section diagnosis differed from the final diagnosis but the discrepancy was neither a false-positive nor a false-negative result. For example, an ovarian carcinoma diagnosed as papillary serous cystadenocarcinoma by frozen section and as endometrioid carcinoma in the final diagnosis would be classified under other diagnostic discrepancy.

Additional information was recorded about the frozen-section diagnosis. Benign diagnoses were further categorized as follows: (1) no pathologic diagnosis or diagnostic tissue received, (2) inflammatory or reactive process, (3) hyperplastic or proliferative process, (4) hamartoma or malformation, (5) benign neoplasm, or (6) nondiagnostic specimen. Similarly, malignant diagnoses were further designated as carcinoma, sarcoma, melanoma, lymphoma or lymphoproliferative, glial neoplasm, or malignant neoplasm, final diagnosis deferred.

Factors contributing to a discrepancy between frozen-section interpretation and final diagnosis were classified as follows: (1)

Table 1.—Distribution of Total, Benign, Malignant, and Deferred Frozen-Section Diagnosis by Tissue Site

Site	Total, No. (%)	Benign, No. (%)	Malignant, No. (%)	Deferred, No. (%)
Breast	**1262** (23.0)	844 (66.9)	404 (32.0)	14 (1.1)

sampling error by the pathologist, (2) sampling error by the surgeon, (3) judgment error by the pathologist, and (4) other.

A sampling error by the pathologist occurred when the lesion was present in the tissue received intraoperatively but was either not specifically selected by the pathologist for frozen section or not observed in the actual frozen-section slides. In the latter case, diagnostic tissue was subsequently detected in deeper sections from the same frozen-section tissue block. A sampling error by the surgeon resulted when the tissue submitted intraoperatively for consultation was not diagnostic, but subsequently submitted tissue from the same site for permanent section evaluation did contain the lesion of interest. A judgment error by the pathologist occurred when the surgical pathology report stated that the diagnostic pathologic process was present in the frozen-section slides examined but was not interpreted correctly during the intraoperative consultation.

Information derived from a review of the pathology reports was encoded for computer-assisted sorting and retrieval. The two-digit Systematized Nomenclature of Medicine system was used for tissue site classification. Some closely related tissue sites were grouped together for convenience.

RESULTS

A total of 70 834 cases were accessioned in the surgical pathology files from 1980 through 1984 at St John's Mercy Medical Center. Of these cases, 4057 (5.7%) had intraoperative frozen sections performed. Many cases required evaluation of more than one tissue block, resulting in a total of 5493 frozen sections that were actually performed.

Table 1 summarizes the distribution of frozen sections by tissue site. Breast, lymph node, and skin account for almost half (48.7%) of the cases. Some individual sites were grouped for convenience; for example, the nervous system included the brain, meninges, pituitary gland, and pineal, spinal, and cranial nerves. In other instances, the grouping was chosen on the basis of the anatomic proximity or histologic similarity of sites in which pathologic processes often obscured certainty of specific site identification. All other sites included those that individually had few frozen sections and neither false-positive nor false-negative diagnoses.

The numbers of benign, malignant, and deferred diagnoses are also given in Table 1. The number of benign frozen-section diagnoses were more often greater than the number of malignant diagnoses except for the liver, in which two thirds of the frozen-section diagnoses were malignant.

The results of the comparison of the frozen-section interpretations with the final pathologic diagnoses are given in Table 2. There was absolute agreement in 5024 (91.5%) of all the sections examined. Frozen-section and final diagnoses disagreed in 373 (6.8%) of the cases. The 96 (1.7%) frozen-section diagnoses that were deferred for permanent sections were excluded from this analysis.

The distribution of the diagnostic discrepancies into false-positive and false-negative categories is given in Table

Table 2.—Comparison of Frozen-Section Interpretations With Final Diagnoses

Site	Agree, No. (%)	Disagree, No. (%)
Breast	1197 (94.8)	51 (4.0)
Lymph node	651 (89.9)	49 (6.8)
Skin	640 (92.9)	42 (6.1)
Soft tissues	331 (89.7)	23 (6.2)
Endometrium	296 (91.9)	24 (7.5)
Thyroid gland	265 (88.3)	28 (9.3)
Ovary	257 (91.1)	25 (8.9)
Lung	237 (91.2)	16 (6.2)

3. Most discrepancies represented minor, insignificant differences in interpretation. Less than half of the cases in which the frozen-section and final diagnoses disagreed were classified as false negative or false positive. False-negative diagnoses were more common for lesions of the lymph node, skin, colorectum, pancreas, and sites that were infrequently evaluated.

The types of error resulting in false-negative frozen-section diagnoses are enumerated in Table 4. Overall, most of the errors (42%) were due to the pathologist's sampling of the specimen. The pathologist's judgment accounted for 40% of the false-negative interpretations. Finally, the surgeon's sampling of tissue was responsible for 18% of the false-negative errors. The sites most prone to sampling problems for the surgeon were the pancreas, bone, joint, and prostate. The pathologist had greatest difficulty in selecting the diagnostic tissue for the frozen-section examination when dealing with sites such as the breast, ovary (especially when large and cystic), lung, and colon. Skin lesions were prone to sampling errors mainly due to the focal positivity of surgical margins.

Of 5493 total frozen sections, there were only eight false-positive diagnoses (0.15%). Table 5 lists the sites of false-positive frozen sections. All but one of these diagnoses were due to judgment errors by pathologists. The single exception resulted from contamination of a lymph node specimen by tissue adherent to the cold probe in the cryostat from a prior case. The other false-positive lymph node diagnosis was due to misinterpretation of a hilar lymph node with anthracotic carbon deposition as metastatic carcinoma. This lymph node accompanied a pneumonectomy specimen that contained squamous cell carcinoma. The one false-positive frozen section of skin was the result of interpretation of actinic keratosis as squamous cell carcinoma in situ. This lesion was at the surgical margin of a specimen that contained a basal cell carcinoma. Further marginal excision was not carried out in this case. An ovarian tumor diagnosed as a borderline mucinous tumor on frozen section was judged to be a mucinous cystadenoma after examining permanent sections. No additional surgery was performed on the basis of the frozen-section diagnosis. A case of organizing pneumonia was misdiagnosed as alveolar carcinoma. The tissue initially submitted for this intraoperative consultation was a specimen obtained by lobectomy. Additional surgery included only a pleural biopsy. There was one case of gastric lymphoid hyperplasia ("pseudolymphoma") associated with ulcer, which was thought to be malignant lymphoma at the time of frozen section. The operative procedure in this case was a subtotal gastrectomy for antral ulcers. A

Table 4.—Summary of Errors Resulting in False-negative Frozen-Section Interpretations

Site	Sampling Error by Pathologist, No. (%)	Sampling Error by Surgeon, No. (%)	Judgment Error, No. (%)

case of pseudoepitheliomatous hyperplasia of the esophagus was diagnosed with frozen section as squamous cell carcinoma. This diagnosis was rendered on the proximal margin of a partial esophagectomy specimen that was removed for squamous cell carcinoma. An additional 1.5-cm portion of esophagus was resected based on this intraoperative diagnosis. Last, a nasal specimen diagnosed as papilloma with focal squamous cell carcinoma in situ intraoperatively was actually an inverted papilloma. Tissue was resected from the nasal cavity, ethmoid sinus, and maxillary sinus in this procedure, and all sites contained inverted papilloma.

COMMENT

The false-positive and false-negative rates, 0.15% and 2.8%, respectively, of our five-year frozen-section audit were below most of the rates previously published.[2,6-8] The overall utilization rate of 5.7% was also in keeping with the recommended rate of 10% or less.[3] The distribution of cases according to tissue site was comparable with other reports in that most of our frozen sections were performed on breast, lymph node, and skin.[4,5,8] The large number of breast and skin frozen sections can be expected, since these two tissue sites together account for 30% of the cases of cancer per year.[9]

Examination of the surgical margins of cutaneous lesions is a necessary intraoperative procedure when surgical cure is to be accomplished with a single visit to the operating room. Similarly, the presence of metastatic tumor in lymph nodes is vital information for most surgical procedures for cancer. Detection of metastases may determine the placement of clips for marking irradiation portals and may influence the extent of surgical procedures.

We believe that the distinction between a benign and malignant lymphoproliferative process is not appropriate at the time of frozen section. Diagnostic difficulties encountered with lymph nodes not altered by metastatic carcinoma or easily recognized infectious processes have been emphasized by other authors.[5,10] In such instances, the pathologist's role should be to determine whether adequate material has been sampled to permit accurate diagnosis on evaluation of properly fixed sections with optimal cytologic presentation.

We anticipated a decrease in the proportion of intraoperative frozen sections performed on breast tissue in comparison with previously published reports,[2,4,5,7,10] since the approach to the patient with breast disease has changed. It is now uncommon, at least in our institution, for patients to undergo a mastectomy following a frozen-section diagnosis of carcinoma from an incisional biopsy during the same anesthesia. Rather, most of our patients with breast lesions initially have an excisional biopsy on an outpatient basis. Further surgery, if required, is done at a later date following discussion of the results of the final pathology report with the patient. Before definitive surgery, alternative methods of management are also considered by the patient and surgeon. The final pathology report of the excisional biopsy specimen is usually available within 24 hours; when surgery is performed on Saturday, the report is available on Monday. Despite these practices, frozen sections are still routinely and unnecessarily requested on breast tissue. The opportunity to obtain fresh tissue for estrogen and progesterone receptors is not missed if a frozen section is not requested. In actual practice, all breast tissue received in our laboratory is examined in the fresh state. Our specimens are transported by way of a mechanical transport system, with a transit time of three minutes from the operating room to the gross pathology laboratory. The pathologist is notified when a breast biopsy specimen is received, and the pathologist then decides whether it is necessary to reserve tissue for hormone receptor analysis. Many breast cancers are grossly obvious and do not require microscopic confirmation. In instances of uncertainty, sufficient tissue for hormone receptor analysis is reserved at −70°C until permanent sections of grossly similar tissue adjacent to the reserved tissue are evaluated. This protocol has eliminated freezing artifact of lesions that are difficult to interpret. The tissue reserved for receptor analysis can be thawed and examined histologically when a diagnosis remains equivocal.

Frozen-section evaluation of breast lesions, therefore, can be an unnecessary expense that may actually hinder

the pathologist from rendering an accurate diagnosis. This is especially true when the quantity of tissue is limited. In addition, every frozen section has a small chance of giving a false-negative diagnosis. With this in mind, frozen-section diagnoses rendered for breast lesions that are clinically or mammographically suspicious are accompanied by a word of caution. No breast lesion can be considered completely benign until the entire specimen has been examined by permanent sections. It seems unnecessary, therefore, to jeopardize an accurate diagnosis and subject the patient to a potential false-negative diagnosis when immediate care will not be affected.

In situations where the lesion is small and cannot be divided for histologic examination and special studies, cytologic preparations are helpful and often diagnostic.[11,12] Either touch preparations or smears of cells exfoliated from the cut surface of the specimen can be used for intraoperative diagnosis, thus sparing the solid tissue for hormone receptor analysis in the case of specimens of breast cancer. In other instances, this same approach is useful to triage tissue for microbiologic culture, special fixatives, procurement for immunocytochemistry, electron microscopy, or whatever is deemed necessary to arrive at a correct final diagnosis.

Another consideration, as addressed by Kindschi,[3] is one of simple economics. Current procedural terminology[13] identifies the activity of intraoperative consultation, intraoperative consultation with frozen section, and performance of each additional frozen section as codes 88329, 88331, and 88332, respectively. The pathologist's professional fees and institutional technical charges associated with these codes will vary. They may add appreciably to patient costs, particularly when multiple frozen sections are required.

The information derived from review of our frozen-section cases agreed with previous similar studies. When confronted with difficult diagnostic decisions, pathologists tend to be appropriately conservative. Our review showed that false-positive diagnoses did not result in excessive additional surgery.

We propose that the most practical and effective use of frozen section will occur in the circumstances in which the surgeon views the pathologist as a consultant and the pathologist is sensitive to the needs of the surgeon. When the pathologist is appropriately informed of pertinent historical information, the therapeutic considerations, and intraoperative findings, an optimal utilization of tissue for accurate diagnosis can be achieved. When a request for an intraoperative frozen section diagnosis is appropriate, the surgeon can be assured that the diagnosis rendered is accurate.

Susie Oberlander prepared the manuscript, Scott W. Prey, MS, provided computer expertise, and B. Balfour Kraemer, MD, and Frederick T. Kraus, MD, provided editorial advice.

Editorial Comment

The study by Prey et al in the accompanying article reconfirms the accuracy of frozen-section diagnosis done in a qualified institution. Of the 0.15% false-positive diagnoses, none involved breast samples, which made up 23% of the sample, and none affected the surgical care of the patients. Frozen section in 1988 is an accurate diagnostic technique on which sound surgical judgment can be made intraoperatively.

The popularity of the two-stage mastectomy, as described by the authors, may be less now than in the recent past. In my practice, more and more women are requesting a breast biopsy and definitive treatment as a single procedure. The patient enters the hospital as an outpatient for the breast biopsy and, if the frozen section gives abnormal results, at that time undergoes the indicated oncologic procedure. Certainly efficient use of medical resources is better served by this process.

Frozen section should be used when the knowledge gained is necessary to direct intraoperative management, such as adequate margins of resection, adequate sampling of lesions that require an operative approach to gain access, and appropriate pathologic study of the fresh tissue. Otherwise, frozen section is not often necessary and should not jeopardize the ability to determine permanent section diagnosis, unless the knowledge gained is critical to immediate surgical care.

DEFINING A NEW STAND

D* FOR EMPIRIC THERAPY

For Infection Following
Complicated Abdominal Surgery

BETTER THAN AMINOGLYCOSIDE COMBINATIONS FOR MOST PATIENTS

For These Reasons...

- ☐ Gram-negative coverage of an aminoglycoside plus
- ☐ Gram-positive coverage of cefazolin plus
- ☐ Anaerobic coverage of clindamycin or metronidazole plus
- ☐ Enterococcal coverage of ampicillin plus
- ☐ Tolerability profile characteristic of beta-lactam antibiotics

...PRIMAXIN Is a Better Choice for Empiric Therapy

Coverage of specified agents is based upon the Microbiology Section of the Prescribing Information as published in the 1988 *Physicians' Desk Reference*®

Data available from Merck Sharp & Dohme, West Point, PA 19486.

PRIMAXIN is contraindicated in patients who have shown hypersensitivity to any component of this product. Before initiating therapy with PRIMAXIN, careful inquiry should be made concerning previous hypersensitivity reactions to penicillins, cephalosporins, other beta-lactams, and other allergens. If an allergic reaction to PRIMAXIN occurs, discontinue the drug. Serious hypersensitivity reactions may require epinephrine and other emergency measures.

In vitro activity does not necessarily imply *in vivo* effectiveness.

*when indicated organisms are suspected at indicated sites

INTRAVENOUS

PRIMAXIN®

(Imipenem-Cilastatin Sodium/MSD)

Please see Brief Summary of Prescribing Information on following page.

Copyright © 1988 by Merck & Co., Inc.

INTRAVENOUS

PRIMAXIN®

(Imipenem-Cilastatin Sodium/MSD)

Contraindications: PRIMAXIN is contraindicated in patients who have shown hypersensitivity to any component of this product.

Warnings: SERIOUS AND OCCASIONALLY FATAL HYPERSENSITIVITY (anaphylactic) REACTIONS HAVE BEEN REPORTED IN PATIENTS RECEIVING THERAPY WITH BETA LACTAMS. THESE REACTIONS ARE MORE APT TO OCCUR IN PERSONS WITH A HISTORY OF SENSITIVITY TO MULTIPLE ALLERGENS.

THERE HAVE BEEN REPORTS OF PATIENTS WITH A HISTORY OF PENICILLIN HYPERSENSITIVITY WHO HAVE EXPERIENCED SEVERE HYPERSENSITIVITY REACTIONS WHEN TREATED WITH ANOTHER BETA LACTAM. BEFORE INITIATING THERAPY WITH 'PRIMAXIN' CAREFUL INQUIRY SHOULD BE MADE CONCERNING PREVIOUS HYPERSENSITIVITY REACTIONS TO PENICILLINS, CEPHALOSPORINS, OTHER BETA LACTAMS, AND OTHER ALLERGENS. IF AN ALLERGIC REACTION TO 'PRIMAXIN' OCCURS, DISCONTINUE THE DRUG. SERIOUS HYPERSENSITIVITY REACTIONS MAY REQUIRE EPINEPHRINE AND OTHER EMERGENCY MEASURES.

Pseudomembranous colitis has been reported with virtually all antibiotics, including PRIMAXIN; therefore it is important to consider its diagnosis in patients who develop diarrhea in association with antibiotic use. This colitis may range in severity from mild to life threatening.

Mild cases of pseudomembranous colitis may respond to drug discontinuance alone. In more severe cases, management may include sigmoidoscopy, appropriate bacteriological studies, fluid, electrolyte, and protein supplementation, and the use of a drug such as oral vancomycin, as indicated. Isolation of the patient may be advisable. Other causes of colitis should also be considered.

Precautions: *General*—CNS adverse experiences such as confusional states, myoclonic activity, and seizures have been reported during treatment with PRIMAXIN, especially when recommended dosages were exceeded. These experiences have occurred most commonly in patients with CNS disorders (e.g., brain lesions or history of seizures) and/or compromised renal function. However, there have been reports of CNS adverse experiences in patients who had no recognized or documented underlying CNS disorder or compromised renal function.

Patients with severe or marked impairment of renal function, whether or not undergoing hemodialysis, had a higher risk of seizure activity when receiving maximum recommended doses than those with no impairment of renal function; therefore, maximum recommended doses should be used only where clearly indicated (see DOSAGE AND ADMINISTRATION).

Patients with creatinine clearances of ≤5 mL/min/1.73 m^2 should not receive PRIMAXIN unless hemodialysis is instituted within 48 hours.

For patients on hemodialysis, PRIMAXIN is recommended only when the benefit outweighs the potential risk of seizures.

Close adherence to the recommended dosage and dosage schedules is urged, especially in patients with known factors that predispose to convulsive activity. Anticonvulsant therapy should be continued in patients with known seizure disorders. If focal tremors, myoclonus, or seizures occur, patients should be evaluated neurologically, placed on anticonvulsant therapy if not already instituted, and the dosage of PRIMAXIN re-examined to determine whether it should be decreased or the antibiotic discontinued.

As with other antibiotics, prolonged use of PRIMAXIN may result in overgrowth of nonsusceptible organisms. Repeated evaluation of the patient's condition is essential. If superinfection occurs during therapy, appropriate measures should be taken. While PRIMAXIN possesses the characteristic low toxicity of the beta-lactam group of antibiotics, periodic assessment of organ system function during prolonged therapy is advisable.

Drug Interactions—Since concomitant administration of PRIMAXIN and probenecid results in only minimal increases in plasma levels of imipenem and plasma half-life, it is not recommended that probenecid be given with PRIMAXIN.

PRIMAXIN should not be mixed with or physically added to other antibiotics. However, PRIMAXIN may be administered concomitantly with other antibiotics, such as aminoglycosides.

Carcinogenesis, Mutagenesis, Impairment of Fertility—Gene toxicity studies were performed in a variety of bacterial and mammalian tests *in vivo* and *in vitro*. The tests were: V79 mammalian cell mutation assay (PRIMAXIN alone and imipenem alone), Ames test (cilastatin sodium alone), unscheduled DNA synthesis assay (PRIMAXIN), and *in vivo* mouse cytogenicity test (PRIMAXIN). None of these tests showed any evidence of genetic damage.

Reproduction tests in male and female rats were performed with PRIMAXIN at dosage levels up to 8 times the usual human dose. Slight decreases in live fetal body weight were restricted to the highest dosage level. No other adverse effects were observed on fertility, reproductive performance, fetal viability, growth, or postnatal development of pups. Similarly, no adverse effects on the fetus or on lactation were observed when PRIMAXIN was administered to rats late in gestation.

Pregnancy—Pregnancy Category C: Teratogenicity studies with cilastatin sodium in rabbits and rats at 10 and 33 times the usual human dose, respectively, showed no evidence of adverse effect on the fetus. No evidence of teratogenicity or adverse effect on postnatal growth or behavior was observed in rats given imipenem at dosage levels up to 30 times the usual human dose. Similarly, no evidence of adverse effect on the fetus was observed in teratology studies in rabbits with imipenem at dosage levels at the usual human dose.

Teratology studies with PRIMAXIN at doses up to 11 times the usual human dose in pregnant mice and rats during the period of major organogenesis revealed no evidence of teratogenicity.

Data from preliminary studies suggest an apparent intolerance to PRIMAXIN (including emesis, inappetence, body weight loss, diarrhea, and death) at doses equivalent to the average human dose in pregnant rabbits and cynomolgus monkeys that is not seen in nonpregnant animals in these or other species. In other studies, PRIMAXIN was well tolerated in equivalent or higher doses (up to 11 times the average human dose) in pregnant rats and mice. Further studies are under way to evaluate these findings.

There are, however, no adequate and well-controlled studies in pregnant women. PRIMAXIN should be used only if the potential benefit justifies the potential risk to the fetus.

Nursing Mothers—It is not known whether this drug is excreted in human milk. Because many drugs are excreted in human milk, caution should be exercised when PRIMAXIN is administered to a nursing woman.

Pediatric Use—Safety and effectiveness in infants and children below 12 years of age have not yet been established.

Adverse Reactions: PRIMAXIN is generally well tolerated. Many of the 1,723 patients treated in clinical trials were severely ill and had multiple background diseases and physiological impairments, making it difficult to determine causal relationship of adverse experiences to therapy with PRIMAXIN.

Local Adverse Reactions—Local adverse clinical reactions that were reported as possibly, probably, or definitely related to therapy with PRIMAXIN were: phlebitis/thrombophlebitis (3.1%), pain at the injection site (0.7%), erythema at the injection site (0.4%), vein induration (0.2%), infused vein infection (0.1%).

Systemic Adverse Reactions—The most frequently reported systemic adverse clinical reactions that were reported as possibly, probably, or definitely related to PRIMAXIN were: nausea (2.0%), diarrhea (1.8%), vomiting (1.5%), rash (0.9%), fever (0.5%), hypotension (0.4%), seizures (0.4%) (see PRECAUTIONS), dizziness (0.3%), pruritus (0.3%), urticaria (0.2%), somnolence (0.2%).

Additional adverse systemic clinical reactions reported as possibly, probably, or definitely drug related occurring in less than 0.2% of the patients or reported since the drug was marketed are listed within each body system in order of decreasing severity: *Gastrointestinal*—pseudomembranous colitis (see WARNINGS), hemorrhagic colitis, gastroenteritis, abdominal pain, glossitis, tongue papillar hypertrophy, heartburn, pharyngeal pain, increased salivation; *CNS*—encephalopathy, tremor, confusion, myoclonus, paresthesia, vertigo, headache, psychic disturbances; *Special Senses*—transient hearing loss in patients with impaired hearing, tinnitus; *Respiratory*—chest discomfort, dyspnea, hyperventilation, thoracic spine pain; *Cardiovascular*—palpitations, tachycardia; *Renal*—oliguria/anuria, polyuria; *Skin*—erythema multiforme, facial edema, flushing, cyanosis, hyperhidrosis, skin texture changes, candidiasis, pruritus vulvae; *Body as a Whole*—polyarthralgia, asthenia/weakness.

Adverse Laboratory Changes—Adverse laboratory changes without regard to drug relationship that were reported during clinical trials or reported since the drug was marketed were: *Hepatic*—increased SGPT, SGOT, alkaline phosphatase, bilirubin, and LDH; *Hemic*—increased eosinophils, positive Coombs test, decreased WBC and neutrophils, including agranulocytosis, increased WBC, increased platelets, decreased platelets, decreased hemoglobin and hematocrit, increased monocytes, abnormal prothrombin time, increased lymphocytes, increased basophils; *Electrolytes*—decreased serum sodium, increased potassium, increased chloride; *Renal*—increased BUN, creatinine; *Urinalysis*—presence of urine protein, urine red blood cells, urine white blood cells, urine casts, urine bilirubin, and urine urobilinogen.

NOTE: Due to the high antimicrobial activity of PRIMAXIN, it is recommended that the maximum total daily dosage not exceed 50 mg/kg/day or 4.0 g/day, whichever is lower.

How Supplied: PRIMAXIN is supplied as a sterile powder mixture in vials, infusion bottles, and single-dose ADD-Vantage®† vials containing imipenem anhydrous and cilastatin sodium as follows: 250 mg imipenem equivalent and 250 mg cilastatin equivalent; 500 mg imipenem equivalent and 500 mg cilastatin equivalent.

Caution: The suspension from vials is not for direct infusion.

Comparison of Antibody Response With Delayed Hypersensitivity in Severely Injured Patients

Michael J. Hershman, FRCS; William G. Cheadle, MD; Sarah H. Appel; Christopher D. George, FRCS; Pattie F. Davidson, RN; Karen M. Cost, PhD; Hiram C. Polk, Jr, MD

• Twenty-seven severely injured patients had antibody response to gram-negative organisms measured of whom 25 also had skin testing. Twenty-three patients (92%) were anergic at admission. Injury Severity Scores were greater in patients who remained anergic for three weeks compared with patients whose skin tests became positive. Patients with major infection had longer anergy duration than uninfected patients. Twenty-two (81%) of 27 anergic patients mounted antibody responses. Initial bacterial contamination determined the clinical outcome and antibody response. Six of eight patients with moderate contamination mounted IgM responses to all organisms and/or an IgG response to *Escherichia coli*, and they remained uninfected. Of the other two patients, one died, and the other developed chronic infection. Seven of eight patients with heavy contamination developed major sepsis despite mounting several antibody responses. Six patients without contamination mounted no antibody responses and remained uninfected.

(*Arch Surg* 1989;124:339-341)

Trauma is the most common cause of death in patients under 35 years of age and the fourth leading cause among all age groups.[1] Despite advances in surgical techniques and antimicrobial therapy, infection remains the major cause of late death following trauma.[2] Inability to eradicate sepsis has turned the surgeon's attention to host-defense mechanisms, and these studies have shown that components of both cell-mediated and humoral immunity systems are affected by trauma.[3]

Cell-mediated immunity may be assessed clinically by using delayed-type hypersensitivity of skin to recall test antigens, and anergy has been associated with both trauma and sepsis.[4,5] Cost et al[6] have previously described a modification of the enzyme-linked immunosorbent assay (ELISA) technique that can be used clinically to detect antibody against whole bacterial organisms. We have previously shown that antibody responses to *Staphylococcus aureus* have correlated well with clinical infection due to this organism and subsequent recovery.[7] The ELISA technique has now been applied to two additional organisms that are representative of those recovered in clinical gram-negative infection, *Escherichia coli* and *Pseudomonas aeruginosa*. These bacteria are common pathogens that affect patients with trauma, and the strains used were isolated from our surgical intensive care unit. This study aimed to define further the role of anergy following trauma and to determine whether trauma and anergy are associated with an inability to mount specific antibody responses to these particular gram-negative organisms. We also aimed to assess serially the gram-negative antibody responses in patients with severe trauma in an attempt to define healthy responses better.

Accepted for publication March 15, 1988.

PATIENTS AND METHODS

Twenty-seven consecutive patients who were admitted to Humana Hospital University, Louisville, and who sustained major trauma that resulted in an Injury Severity Score (ISS) of at least 20, were studied. Patients with a medical history of myocardial infarction, organ failure, neoplastic disease, or current immunosuppressive therapy (steroids or cytotoxic drugs) were excluded. Patients who were transferred from other centers after initial stabilization were accepted; however, those patients who were transferred after prolonged care were excluded. Informed consent was obtained from the patient or relatives in all cases. There were 13 patients who sustained blunt trauma, 12 who sustained penetrating trauma, and two who had major burns.

To allow more meaningful comparisons between equivalent injuries in patients of different ages, the concept of expressing the ISS as a percentage of the 50% lethal dose of injury for age was used.[8,9] Using a probit fit of burn mortality, Bull[8] developed LD_{50} values for three separate age ranges. Individual percentage of these LD_{50} values were calculated by dividing the ISS for each patient by the appropriate LD_{50} for age and expressed as a percentage ($\%LD_{50}$). Contamination that was present at the time of admission or surgery was graded: massive soft-tissue contamination or large-bowel spillage (2+); minor soft-tissue, intrathoracic, or abdominal contamination (1+); or no contamination (0).

Infectious events in these patients were classified into major and minor groups by usual clinical criteria. Major events included every example of bacteremia, all of which were associated with definable clinical problems, major wound infection, intra-abdominal or other serous cavity abscess, and any situation in which reoperation for suspected infection was undertaken. Minor events included urinary tract infections and minor wound sepsis. Some positive cultures of pathogenic bacteria from orifices or sites that were unassociated with any sign of clinical sepsis were reported but not classified as an infectious event. Infections were categorized as "early," that is, occurring within the first week following trauma, or "late," occurring after the first week.

Venous blood samples were obtained for immunological studies from each patient within 24 hours of admission and at weekly intervals during their hospital course or until a positive skin test was elicited. The three recall antigens used were *Candida albicans* (Center Laboratories, New York), tuberculin purified protein derivative (Aplisol, Parke-Davis, Morris Plains, NJ), and *Trichophyton* (Berkeley Biological, Berkeley, Calif). Intradermal injections of 0.1 mL of each antigen were administered and read by the same person 24, 48, and 72 hours later. A skin test was considered positive if the diameter of induration was greater than 5 mm for *Candida* and *Trichophyton*, and greater than 10 mm for tuberculin purified protein derivative. Patients were classified as normal if they demonstrated a positive response to any one of the recall antigens. Patients with no positive responses were classified as anergic.

The IgG and IgM antibodies to one strain of *E coli* and three strains of *P aeruginosa* (0 serotypes: M, E, and EG) were detected with the use of an ELISA technique. In the development of the ELISA technique, we had shown that both IgG and IgM responses to several strains of *E coli* were quantitatively very similar; therefore, strain O*;K*:NM was considered to be representative of the entire *E coli* species. Antibody response to various *Pseudomonas* strains were more variable; thus, three strains of this organism were used.[6] These organisms were clinical isolates from our surgical intensive care unit. The ELISA procedure that was

*ISS indicates Injury Severity Score; %LD_{50}, percent lethal dose of injury for age; ELISA, enzyme-linked immunosorbent assay; and PAN, response of *all* four IgM antibodies.

†Early indicates occurring within the first week of trauma; late, occurring after one week of trauma.

‡Minus sign indicates negative response; plus sign, positive response.

§Plus sign indicates injury day that skin test became positive; greater than sign, duration of recorded anergy.

‖Patient died.

¶1+ indicates minor soft-tissue, intrathoracic, or abdominal contamination; 2+, massive soft-tissue contamination or large-bowel spillage.

used was modified from a method that was developed and validated in our laboratory.[6] The assay was performed in flat-bottomed, 96-well polystyrene microtest plates (Flow Laboratories, Inc, Hamden, Conn). Formaldehyde solution–killed bacterial suspensions of the test organisms in carbonate buffer (0.05 mol/L, pH 9.6) were added to the wells in 200-μL aliquots and incubated for three hours at 37°C. After washing the plate with phosphate-buffered saline solution with 0.02% sodium azide added, this solution with 0.5% bovine serum albumin (BSA) was added to each well and incubated for 90 minutes at 27°C. After a second wash with phosphate-buffered saline solution with 0.05% polysorbate 20 (Tween 20) and 0.02% sodium azide (PTA), 200 μL of test serum, diluted 1:200 in PTA:BSA, was added to each well and incubated for two hours at 27°C. After a third wash with PTA, alkaline phosphatase–labeled goat anti–human IgG and IgM (Sigma Chemical Co, St Louis) were added in a 1:1000 dilution in PTA-BSA and incubated for 15 to 18 hours at 27°C. After a final wash with PTA, 200 μL of nitrophenol substrate (Sigma), 1 mg/mL in carbonate buffer with 0.001-mol/L magnesium chloride was added to each well. The plates were incubated for 60 minutes at 27°C, and the reaction then was stopped by the addition of 50 μL of 1N sodium hydroxide to each well. The optical density (OD) of each well was measured photometrically at 410 nm with a rapid microplate reader (Mini-Reader, Dynatech Laboratories, Inc, Alexandria, Va) as originally reported by Cost et al.[6] Controls for each plate included wells with antigen but no serum and wells with reference serum and antigen. The control serum was obtained from a healthy laboratory worker whose immunoglobulin levels were documented within the normal range as tested by radial immunodiffusion (Kallestead Laboratories, Chaska, Minn). This laboratory worker was also shown to have antibodies present to all test organisms that were used. Patients' sera were tested in quadruplicate for each of the three antibody classes against each of the four organisms, and the mean OD was recorded.

To minimize intrinsic variation with the ELISA, the following standardization procedure was used. The OD that was recorded for the reference serum in the first assay that was performed was designated as a standard and used to correct data from all subsequent assays. In cases in which the OD reading was off scale, the assay was repeated by using patient's serum and control serum, diluted to 1:400 in PTA-BSA.

A twofold increase in OD units, with the second value reaching a minimum of 0.5 OD units, was defined as a positive response. This had to occur within two weeks for IgM and within three weeks for IgG measurements. A threefold increase of IgG in three weeks was considered a positive response. Responses were divided into early, which commenced within the first week after injury, or late, which commenced subsequent to the first week after injury. The late responses were classified as appropriate or inappropriate to the documented infection. Wilcoxon rank-sum tests were used to compare median anergy duration, and Student's *t* tests were used to compare mean ELISA scores.

RESULTS

Twenty-seven patients were studied. The mean ISS was 38 (range, 24 to 50), and the %LD_{50} was 108 (range, 60 to 141). Fourteen patients developed a major infection, ten developed a minor infection, and three had no infection.

Skin-testing data were available for 25 patients, as two patients sustained severe burns, which precluded application of the tests. Trauma was associated with anergy, as 23 patients (92%) were anergic at admission to the hospital. Increasingly severe injury was associated with a longer duration of anergy. Of the 23 patients who were anergic at admission, seven had skin tests that became positive within three weeks of injury, ten patients remained anergic for longer than three weeks, and six patients were not tested for as long as three weeks. The %LD_{50} of patients whose skin tests became positive within three weeks (median = 80) was significantly less than the %LD_{50} of the patients who remained anergic for greater than three weeks (median = 103) ($P<.04$). Twelve patients who were anergic at admission developed major sepsis, two had minor septic episodes, and nine had no infection. Although absence of response to the recall antigens at admission did not predict septic episodes, major sepsis was associated with prolonged anergy. When the last recorded day of anergy was considered, the group of patients who had a major infection had a duration of anergy (median = 22) that was significantly greater than the no-infection group (median = 13) ($P<.05$). Both groups had similar median %LD_{50} values, which were 87 for the septic group and 86 for the no-infection group.

Comparison with the ELISA data (Table) showed that patients were able to mount antibody responses in the face of continuing skin test anergy. One patient mounted multiple antibody responses despite remaining anergic for 86 days. Twenty-two (82%) of the 27 patients had early antibody responses. Of those 22 patients, 19 had IgM responses, ten had IgG responses, and seven had both. The 22 patients had a total of 61 separate early antibody responses, of which 14 (23%) were IgG, and 47 (77%) were IgM. The early IgG responses were usually to *E coli* (nine

of 14 responses), while the early IgM responses were usually to one of the *Pseudomonas* organisms (34 of 47 responses). All patients who developed a major infection had either *E coli* or *Pseudomonas* isolated by culture.

We observed the importance of degree of contamination and identified specific antibody responses that occurred in patients who coped with their infection well. These included an IgG response to *E coli* alone and IgM responses to all four organisms. Six patients in the no-contamination group had no antibody response and did not develop infection. Six of eight patients in the moderate-contamination group mounted antibody responses either to *E coli* or IgM to all four organisms and did not develop early infection. Of the other two patients in this group, one died and the other developed chronic infection of six months' duration. All patients with severe contamination became infected, except one who died three days after injury.

There were 20 late ELISA responses that were defined as commencing at least one week after injury. Fourteen of these responses occurred synchronously with infection.

COMMENT

Trauma[10] and operation[11,12] have both been shown to depress cell-mediated immunity as demonstrated by absence of response to recall skin test antigens (anergy). The results of our study confirmed that severe trauma was associated with anergy, as 23 (92%) of these patients were anergic as compared with 12% of a routine elective surgical population.[5] We found that the duration of the anergic response correlated closely to the $\%LD_{50}$ for our patient population. The degree of anergy has been associated with both age[13] and severity of trauma.[10,13]

These results indicate that the presence of anergy at admission was not predictive of subsequent major septic episodes following severe trauma, as almost all patients were anergic but only half of them developed a major infection. In fact, one of the two patients who were reactive at admission developed major sepsis. Conflicting reports are available in the literature that both support an association of anergy with septic episodes[4,5,13] and others that have shown no predictive value of anergic skin tests.[14,15] Our data would suggest, though, that major sepsis does prolong the anergic state. Also, the duration of anergy correlates with injury severity and the age of the patient as shown by the $\%LD_{50}$. The recall antigens that were used in this study reliably assessed anergy in repetitive testing. Our decision not to use two other commonly used antigens, streptokinase-streptodornase (Varidase) and mumps, was based on previously voiced reservations regarding their value and reliability in repetitive skin testing.[12]

The presence of anergy did not impair the ability of most patients to mount an antibody response, as early antibody production against *E coli* and the three *Pseudomonas* organisms was seen in 22 of the 27 patients. Most patients had IgM responses (19/22), and about half of them demonstrated IgG responses to *E coli* (10/22). Only two patients developed IgG responses to *Pseudomonas*. The degree of bacterial contamination at initial injury was a major determinant of antibody response and clinical outcome. In the group with no contamination, six patients did not mount an antibody response against the organisms tested, nor developed infection. Antibody response may have been unnecessary in these patients as they would not have become infected. All patients with severe contamination, however, developed infection irrespective of antibody response, except the one patient who died early after admission. In the presence of moderate contamination, IgG response to *E coli* and/or IgM responses to all four organisms may have been beneficial, as six patients had such responses and did not develop early infection. Of the other two patients in this particular group who did not mount such antibody responses, one died and the other developed chronic infection of six months' duration. Confirmation of the apparent protective nature of these responses in the face of moderate contamination will require further study.

The ELISA reported in this article appeared to characterize reliably antibody response to *Pseudomonas* and *E coli*. Indeed, ELISA techniques have recently gained acceptance in the clinical setting as sensitive methods for the determination of antibodies to a wide variety of bacterial antigens. The advantages over conventional techniques, such as agglutination and complement fixation, include relative simplicity, high sensitivity, and the ability to detect antibodies of specific immunoglobulin classes.[6,16] Future developments in ELISA techniques may be extended to immunoglobulin subclasses, specific defects of which have been associated with recurrent infections.[17]

The ability of patients with depressed cellular immunity, as measured by skin testing, to mount an antibody response demonstrates a potentially beneficial aspect of humoral immunity in the prevention of infection following major trauma. The level of contamination present at admission is of paramount importance, although age and severity of injury as shown by $\%LD_{50}$ are also critical. The IgM response to moderate contamination appears to be beneficial in the prevention of early infection. This may be of greater predictive value in larger groups of patients than delayed hypersensitivity skin testing, which appears to be depressed in severely injured patients.

The authors wish to acknowledge Lloyd MacLean, MD, professor of surgery, McGill University and surgeon in chief, Royal Victoria Hospital, Montreal, for his help in review of this manuscript.

Let the new *Guides to the Evaluation of Permanent Impairment* guide your evaluation.

How impaired is impaired?

New...expanded...easier to use...*Guides to the Evaluation of Permanent Impairment,* third edition, is available *now.*

As valuable as ever...the *Guides* offers a standardized method for the medical evaluation of patient impairment, *and* a common language for use among all those involved in the evaluation process. *Even better than before*...the new *Guides* includes: ☐ a more accurate method of measuring *spinal impairment* using inclinometers ☐ pie graphs for quick determination of degree of *upper extremity impairment* ☐ new binocular grid for testing *visual fields,* and more.

Important Note: This edition now mandated or recommended for use in 35 U.S. states and 5 Canadian provinces.

The sooner you order...the sooner you'll receive your copy of the third edition of *Guides to the Evaluation of Permanent Impairment.* See coupon below for details.

THE DIRTY TRUTH ABOUT SURGICAL GLOVES

All surgical gloves are sterile. That's a fact. But, the truth is that most gloves must be "scrubbed" or wiped thoroughly before surgery. The reasons? Actually, there is only one reason. Powder.

Whether used on the inside or outside surface, talc, starch, silica or other powders are linked to a variety of complications: granulomatous reactions, peritonitis, adhesions and increased incidence of infection in the patient and dermatitis for the physician and nurse. Powders also contaminate OR equipment, sutures, microscope lenses and test procedures.

The only way to eliminate powder-related problems is to eliminate powder. While some powders are the residue of the manufacturing process, most gloves require powder as a donning lubricant. And, powders can leak from the interior through perforations and tears, can spill from the cuff or escape during a glove change. Regardless of how powder gets on the glove, before surgery it must be removed.

SEM (1000X) of surface of commercially available glove showing cornstarch particles and a surface perforation.

Methods used to remove powder can actually introduce new particulates or may compromise sterility. And, routine glove scrub methods can leave residual powder clinging to the glove surface.

Before scrub: SEM (1000X) of surface of commercially available glove employing cornstarch.

After scrub: SEM (1000X) of same brand glove following 30–40 second warm water scrub followed by wipe with a lint-free towel. SEM shows residual cornstarch particles on the surface.

So, considering the potential risks, why use powder at all?

Now there is PRISTINE,™ the powder-free surgical glove. With a patented, friction-resistant inner surface, donning is smooth and simple. And, with no powders, talcs, starches, silicas or donning lubricants of any kind, using PRISTINE means no glove scrub, powder dermatitis or powder-related post-op complications.

PRISTINE's pure latex construction is durable yet thin enough to give you the tactile sensitivity you need for handling the most delicate instruments. And, the texturized exterior ensures maximum control.

Surface of a PRISTINE powder-free surgical glove. SEM (1000X) shows no foreign body or particulate contamination.

So, for a free sample of PRISTINE gloves, mail the coupon below. To order and for more information, contact World Medical Supply, (800) 545-5475, in CA (800) 547-3366.

Try PRISTINE and discover the glove that is missing only one thing—powder.

PRISTINE.™ The Surgeon's Glove.

Yes. I would like to try PRISTINE gloves.

Computed Tomography and Diagnostic Peritoneal Lavage in Blunt Abdominal Trauma

Their Combined Role

Paul A. Kearney, Jr, MD; Thomas Vahey, MD; Richard E. Burney, MD; Gary Glazer, MD

• We reviewed medical records and films of all 196 trauma patients who underwent computed tomography (CT) between June 1982 and October 1986 to see whether CT achieved the level of accuracy attributed to it, whether diagnostic peritoneal lavage (DPL) performed in conjunction with CT was a useful diagnostic test for blunt abdominal trauma, and whether laparotomy was mandatory when pelvic fluid collections were seen by CT after blunt trauma. A total of 36 patients underwent DPL, 29 before and seven after CT. There were seven false-negative CTs that were clinically significant. Diagnostic peritoneal lavage was positive in three patients who had false-negative CTs. Although overall accuracy was excellent, CT was not reliable in detecting bowel injury. Diagnostic peritoneal lavage was helpful in detecting injuries missed by CT. Most stable patients with moderate or large intraperitoneal fluid collections on CT accompanying solid viscus injury were treated successfully without laparotomy.

(*Arch Surg* 1989;124:344-347)

Since it became widely available after 1980, abdominopelvic computed tomographic (CT) scanning has rapidly gained in popularity as a method of examining the multiply injured patient[1] and has been reported to be replacing all other tests commonly used for the diagnosis of blunt abdominal trauma, including diagnostic peritoneal lavage (DPL).[2] Proposed advantages of CT scanning over DPL include organ specificity, improved diagnosis of extra-abdominal injuries, and a reduction in unnecessary laparotomies for blunt trauma.[3-5] At the same time, delay, cost, lack of sensitivity for hollow viscus injuries, and unavailability of high-resolution equipment or personnel experienced in interpretation have all been cited as potential weaknesses of CT scanning.[6-8] A high rate of false-negative CT findings has been reported by other investigators,[6,7,9] who have advocated the continued use of peritoneal lavage. There is, as a result, lack of agreement regarding the appropriate roles of CT and DPL in the diagnostic evaluation of the abdomen in the multiply injured patient.

We have used CT with *increasing* frequency and DPL with *decreasing* frequency in the evaluation of blunt abdominal trauma since 1982. The chief purpose of this study was to evaluate whether CT achieved the high sensitivity, specificity, and reduction in the nontherapeutic laparotomy rates that have been attributed to it. In addition, we wished to find out whether DPL performed in conjunction with CT was a useful diagnostic test in patients with blunt abdominal trauma, and whether moderate to large pelvic fluid collections detected by CT in injured patients were a mandatory indication for laparotomy.

PATIENTS AND METHODS

The records of all 199 patients undergoing CT scanning for blunt abdominal trauma between June 1, 1982, and Oct 31, 1986, were searched. Both the medical records and the CT films were available for review in 196 (98%) of the patients. Data collection included mechanism of injury, indication for CT scan and/or DPL, presence of a pelvic fluid collection on CT scan, quality of scan, and outcome. The sensitivity, specificity, and diagnostic accuracy of both peritoneal lavage and CT scan were determined by laparotomy, clinical outcome, and/or repeated CT.

All CT scans were performed according to a standard protocol, which calls for oral contrast medium to be administered 30 to 40 minutes prior to scanning, followed by a bolus of intravenous (IV) and oral contrast media at the time of the CT scan. Scans were taken at 1-cm intervals through the lower part of the chest, the abdominal cavity, and the pelvis. Scan quality was recorded at the time of the scan, as were all scans in which oral and/or IV contrast agents were omitted. All scans were reviewed by experienced staff radiologists, if not at the time the scan was done, then within 12 hours. A small number (5%) of the CT scans early in the period of study were performed on an early-model scanner (GE 8800), which has a scan time of 5.6 s. The majority of scans were done on the more rapid late-model scanner (GE 9800), which has a scan time of 2 s.

Accepted for publication April 29, 1988.

From the Departments of Surgery (Drs Kearney and Burney) and Radiology (Drs Vahey and Glazer), University of Michigan, Ann Arbor. Dr Kearney is now with the Department of Surgery, University of Kentucky, Louisville.

Diagnostic peritoneal lavage was performed using an open lavage technique. Both the bladder and stomach were decompressed prior to insertion of the lavage catheter. If initial aspiration for blood was negative, 1 L of Ringer's lactate was infused through a peritoneal dialysis catheter directed into the pelvis under direct vision. Criteria for a positive lavage were those generally considered significant for intra-abdominal injury.[10]

RESULTS

Of the 196 scans available for review, 119 (61%) were of adults and 77 (39%) were of children. All patients were stable (86%) or rapidly stabilized (14%) in the emergency department prior to abdominopelvic CT scan. Motor vehicle collisions accounted for two thirds of the injuries in patients who underwent CT evaluation. Other causes of injury included pedestrian accidents, falls, motorcycle and bicycle accidents, assaults, and other accidents. The most common indications for CT were altered mental status (39%), equivocal abdominal examination results (37%), and age less than 16 years (19%). The remaining examinations were done in patients with acute spinal cord injury (3%) and patients with hematuria (2%).

The distribution of injuries and accuracy of detection by CT scan are shown in Table 1. There was one false-positive diagnosis, an apparent ruptured diaphragm that was not present at operation (the patient also had splenic rupture correctly identified by CT). There were seven false-negative scans. Sensitivity of CT was 96.5%, specificity 99.5%, and accuracy 96%.

Thirty-six patients underwent DPL as well as CT. For 29 patients, DPL was done *prior to* CT, usually because of a high index of suspicion of intraperitoneal hemorrhage on admission or initially unstable vital signs. The remaining seven patients underwent DPL *after* CT, usually because of a change in clinical signs or symptoms. There were three false-negative results and no false-positives.

Table 2 summarizes all of the instances in which significant intra-abdominal injuries were missed by CT, DPL, or both. Diagnostic peritoneal lavage was performed in five patients with false-negative CT scans: before CT in three and after CT in two. In three of these patients DPL was positive, but in the other two, DPL was falsely negative. One of the patients with false-negative results by both CT and DPL had a ruptured spleen, the other had a diaphragmatic tear and an inferior vena cava laceration. In the latter patient, however, CT scan correctly identified a splenic injury for which the patient underwent exploratory surgery, which led to the other diagnoses.

The one remaining instance in which DPL results were false-negative occurred in a 54-year-old motor vehicle accident victim. A CT scan done following DPL demonstrated an injury to the distal ileum, which was repaired in the operating room.

The two other false-negative CT scans occurred in patients who did not have DPL. One patient had a sigmoid hematoma discovered incidentally during a laparotomy for a ruptured spleen. This sigmoid lesion was identifiable on CT but had been overlooked on the initial interpretation. Another patient, although never requiring operation, had a clinical course consistent with traumatic pancreatitis. Initially his scan was interpreted as normal, but retrospective review identified a pancreatic contusion.

Bowel injuries occurred in five patients in this series (2.5%): three had perforations of the small bowel and two had mesenteric injuries. However, CT scan detected only one of the five; DPL was carried out on four of these patients and detected three of these injuries.

Table 1.—Intra- and Extra-abdominal Injuries Identified by Abdominopelvic Computed Tomographic (CT) Scan and Operation

	CT				Operation
	True-Positive	True-Negative	False-Positive	False-Negative	False-Negative
Spleen	22	172	0	1	1*
Liver	21	173	0	1†	1*
Bowel	1	191	0	4	0
Diaphragm	1	193	1	1‡	0
Kidney	28§	168	0	0	...
Pancreas	2	193	0	1	...
Lung	42	154	0	0	...
Bone	46	150	0	0	...

*Clearly identified by CT but not identifiable at operation.
†Also had ruptured mesenteric hematoma.
‡Also had a missed inferior vena cava laceration.
§Includes four incidental renal lesions: one hypernephroma, one angiolipoma, and two renal cysts.

Two patients were considered to have false-negative surgical results. One patient had a large intrahepatic hematoma with contusion by CT scan that could not be identified at laparotomy (for ruptured spleen). The second patient had intrasplenic hematoma and diaphragm rupture identified by CT. At laparotomy, no superficial splenic injury could be identified. Follow-up CT scans, however, clearly showed a resolving intrasplenic hematoma.

A moderate fluid collection on CT was defined as fluid present in more than one paracolic gutter or perihepatic or subdiaphragmatic space. A large fluid collection was defined as filling the pelvis and at least one other gutter or space. There were 23 patients who had the CT findings of liver and/or splenic injury accompanied by moderate to large amounts of pelvic fluid. Only one (12%) of eight children in this group and six (40%) of 15 adults required surgical exploration for their injuries. The blood transfusion requirement of those who did not require surgery was significantly less (2.6 ± 1.5 U) than that of those who were operated on (6.5 ± 3 U; $P = .005$).

The overall outcome in this group of patients was good. One hundred sixty-two patients (83%) were discharged alive and well. Twenty-six patients (13%) had poor outcomes, in most instances secondary to significant head or spinal cord injuries. Significant morbidity because of a delay in diagnosis or treatment occurred in only two patients (patients 1 and 5, Table 2). There were eight deaths (4%), none the direct result of an incorrect CT scan or DPL interpretation.

Scan quality was judged to be good or excellent in 190 (96%) of the studies. The majority of scans were performed on the faster scanner (95%). All of the false-negative CT scans except one (patient 3, Table 2) occurred while using the faster scanner. Ninety percent of the patients received oral contrast medium and 95% received IV contrast medium. Both contrast agents were omitted in only two patients (1%). This contributed to a false-negative study in one patient (patient 3, Table 2). No nontherapeutic laparotomies were performed.

The charge for abdominopelvic CT scanning is $946. The average time from ordering of scan to completion averaged 2.5 to three hours, with actual scan times ranging from 30 to 60 minutes. The charge for DPL is $146; the average time to completion was 30 minutes.

COMMENT

The unreliability of physical examination in detecting the intra-abdominal injury in the multiply injured patient is well recognized.[10,11] Liberal use of DPL substantially reduced the morbidity and mortality of unrecognized abdominal hemorrhage, while maintaining an acceptable rate for nontherapeutic laparotomy.[10,12-14] Nevertheless, DPL remains an invasive procedure and does not provide the kind of specific information about the location or extent of organ injury that became available with CT scanning.[1,3-5] It has been a matter of debate whether CT can or should completely replace DPL for the diagnosis of abdominal trauma in stable, multiply injured patients.

A protocol was developed by us in 1982, calling for DPL to be carried out after CT in stable patients, to address the question of whether CT could replace DPL in the diagnosis of blunt abdominal trauma. We soon discovered that DPL and CT were being carried out for different reasons, and that it was hard to convince participants that DPL was necessary in patients with a normal CT scan, making completion of the protocol impossible. We also discovered that, depending on the setting and clinical course, both DPL and CT might be called for.

This study was undertaken first to assess the accuracy of CT in the diagnosis of stable trauma patients and, second, to find out what the contribution of DPL had been in the evaluation of these patients. The findings suggest that, despite the excellent results of CT in detecting most intra-abdominal injuries, a small but clinically important number of critical injuries were missed by CT. In our hands, despite the increasing enthusiasm for CT, DPL remained an important adjunctive procedure, particularly in the detection of bowel injury. This was true regardless of whether DPL was carried out before or after CT.

Federle[4,5,15] has reported a high sensitivity and specificity for CT scanning in detecting hollow viscus injury. We were unable to confirm this finding. Four of five bowel injuries were missed by CT, despite good-quality images and interpretation by experienced radiologists. Even retrospective review of these scans failed to change the original interpretation. We concur with Marx et al[7] that CT scanning is unreliable for hollow viscus injury. When there has been a focal concentration of force against the abdomen, as with a high-riding seat belt or the direct blow of a handlebar or a nightstick, we would recommend performing DPL in addition to CT because of the higher incidence of bowel injury in these situations.

Another important finding of this study is that pelvic fluid collections seen on CT scan in association with hepatic or splenic injury are not necessarily a mandatory indication for laparotomy, as has been suggested by a study in which need for operation was analyzed on the basis of quantification of hemoperitoneum by CT scan.[16] In that report, only 11 of 273 patients with small amounts of intraperitoneal blood required operation, whereas 28 of 30 with moderate or large intraperitoneal hemorrhage did. This was particularly true in the presence of hepatic injury.[4,5,17,18] Fluid collections confined to the perisplenic, perihepatic, or subhepatic space (Morison's pouch) or to the left or right paracolic gutter were all considered to be small intraperitoneal collections. Moderate hemoperitoneum consisted of blood in two or more of these locations. Intraperitoneal fluid collections were considered large (500 mL or more) when pelvic fluid was accompanied by blood in one or more of the above locations.

We did not find quantification of intraperitoneal hemorrhage to be as useful in determining the need for surgical intervention. Hemodynamic stability, transfusion requirement (significantly less in those patients treated nonoperatively), and clinical course were better indicators. Only 13 (7%) of 197 patients in this study required laparotomy for their injuries. Seven of these had moderate to large intraperitoneal fluid collections as indicated by CT. Had the rule of mandatory laparotomy for moderate or large intraperitoneal fluid collections been followed, 16 additional laparotomies would have been done, most likely without benefit. Only six (40%) of 15 adults and one of eight children with liver and/or spleen injuries and with moderate to large abdominal fluid collections required laparotomy.

Computed tomographic scanning for blunt abdominal trauma was not a rapid study in our hands, because of the requirement for oral contrast medium and because of the delays inherent in scheduling and moving multiply injured patients to the radiology suite and back. Intravenous and oral contrast enhancement is important, however, to get the most information from a CT scan, particularly when injury to the pancreas, duodenum, or small bowel is in question.[1-5] One of the seven false-negative evaluations in this study probably resulted from the omission of administration of oral and intravenous contrast media.

It has been recommended that CT scanning precede DPL, because the presence of lavage fluid in the peritoneal cavity may interfere with scan interpretation.[2,5] This has discouraged the use of DPL in situations in which it might be helpful but CT was also likely to be done, as in a patient with blunt trauma, abdominal pain, and hematuria. In this series, when DPL preceded CT it did not interfere with interpretation of the CT scan. There were no false-negative or false-positive results that could be attributed to prior DPL, even after retrospective review. The radiologist was informed that DPL had been carried out, and liberal use of density readings helped to differentiate lavage fluid from

Table 2.—Patients With False-negative Computed Tomography (CT) or Diagnostic Peritoneal Lavage (DPL) Results

Patient/ Age, y	CT Scan Result	DPL Result	Findings at Surgery
1/73	False-negative	Positive after CT	Lacerated jejunum
2/48	False-negative*	Positive before CT	Ruptured duodenum
3/3 mo	False-negative†	Positive after CT	Ruptured mesenteric hematoma, contusion caudate lobe, liver
4/54	Positive	False-negative before CT	Lacerated distal ileum
5/73	False-negative	False-negative before CT	Ruptured spleen
6/41	False-negative*	False-negative before CT	Ruptured diaphragm, lacerated inferior vena cava
7/57	False-negative*	Not done	Sigmoid mesenteric hematoma
8/36	False-negative	Not done	Pancreatic contusion

*Other positive intra-abdominal findings.
†No oral or intravenous contrast medium used.

blood or intestinal contents. Computed tomographic scan correctly diagnosed a distal ileal laceration in a patient with a prior false-negative lavage by using density readings to identify intestinal contents in the pelvis.

There have been a number of attempts to compare abdominal CT and DPL.[6,7,9,19] The issue remains controversial because direct comparison of CT and DPL is probably not possible, except for a very small number of narrowly defined diagnostic questions. The two tests are called for in similar but not identical situations and provide different kinds of information. The results of this study suggest that there are frequent situations in which additional information can be gained from one study even though the other has been done. Neither appears to be completely reliable in the detection of occult bowel injury, but the combination detects more injuries than either study alone. This suggests that CT scanning and DPL are more complementary than they are competing procedures, and they should be thought of and used in this way.

In summary, the results of this study of 196 patients with blunt abdominal trauma or multiple injuries confirm the overall accuracy of CT to be excellent for both intra- and extra-abdominal injuries, but because not all patients can wait for CT, and because a small number of critical injuries may still be missed, DPL should continue to play an important adjunctive role, particularly when bowel injury is suspected. While CT should generally be performed first, the combination can be used effectively in either order. We have not found the presence of moderate to large peritoneal fluid collections associated with solid organ injury to be a reliable indication for laparotomy in the stable trauma patient, and we believe that other clinical indications and clinical course remain the best determinants.

Invited Editorial Comment

The issue of CT scanning vs DPL in the evaluation of abdominal trauma remains highly controversial. From 1982 to 1986, largely as a result of impressive data emerging from the San Francisco General Hospital, the pendulum swung from an aggressive DPL policy to one of exclusive CT scanning in many regions of the United States. During this learning curve, there was greater patient morbidity resulting from delayed laparotomy due to lack of CT sensitivity than to unnecessary laparotomy due to lack of DPL specificity. The above clinical review joins other recent studies emphasizing that these diagnostic tests are not mutually exclusive but rather complementary. There is no question that DPL is extremely reliable in confirming free intraperitoneal bleeding but that it does not quantitate or qualify the source of hemorrhage. Moreover, DPL will not signal those injuries confined to the retroperitoneum. On the other hand, CT scanning has consistently failed with acute pancreatic trauma as well as hollow visceral disruption. Thus, the germane issue is not CT scanning vs DPL, but rather when to employ these tests and how to use the information provided by them. The authors propose that free intraperitoneal blood identified in the pelvic cul-de-sac by CT (>500 mL) does not preclude nonoperative management of liver and splenic injuries. Clearly the long-term risks of blood transfusion must be factored into the cost-benefit equation. But the same logic should apply to the hemodynamically stable patient from whom free blood is aspirated in the emergency department. Further chemical analysis of this blood may identify otherwise occult gut injury. Considering the added expense and obligatory time for CT scanning, the corollary is why not employ DPL as the screening test and reserve CT to further characterize suspected visceral injury? In either case, the above review underscores the prevailing consensus that ultimate patient care will improve with recognition of the complementary rather than competitive roles of CT scanning and DPL.

The Training and Utilization of Surgical Physician Assistants

A Retrospective Study

Linda Ballard Brandt; Malcolm S. Beinfield, MD; Horace A. Laffaye, MD; Arthur E. Baue, MD

• A community hospital's search for qualified surgical house staff in 1975 led to the development of a postgraduate residency program in surgery for physician assistants. Eleven years after its inception, the program's purpose and structure were reviewed, and its alumni, goals, and contributions were evaluated. A 1987 alumni survey provided data to assess the value of residency training to current employment and job satisfaction.

(*Arch Surg* 1989;124:348-351)

When approval of its physician surgical residency program was disallowed in 1975, Norwalk (Conn) Hospital was faced with the dilemma of providing surgical house staff for inhouse patient care.[1] Its solution was the exclusive use and training of physician assistants (PAs) in surgery.

The decision to develop a postgraduate program to recruit and train PAs as surgical house staff was not made lightly by this 427-bed community hospital in southwestern Connecticut. Members of Norwalk Hospital's Department of Surgery, the chief executive officer, and the chairman of the Department of Nursing joined forces with the chairman of the surgical department and Section of Plastic Surgery at Yale University School of Medicine, New Haven, Conn, to identify the hospital's needs and goals and to assess the role of the PA in other settings. A training program specific to PAs that would expand on their undergraduate PA education was considered essential. This involved identifying inherent differences between the training and utilization of physician residents and that of PA residents. Whereas the physician surgical resident trains to develop the skills necessary to become an independent operating surgeon, the surgical PA is trained to develop skills and judgment as a surgeon's assistant, a qualified team member.[2]

When Norwalk Hospital developed its PA Surgical Residency Program, the PA profession was little more than ten years old. In 1974, about 75% of all PAs worked in primary care settings. Of those employed in specialty areas, approximately 19% were in surgery.[3] A primary care medical background was considered essential in preparing these individuals for the decision-making process involved in the management of surgical patients.[3] Norwalk Hospital's first class of PA surgical residents in 1976 was handpicked for interpersonal skills, academic excellence, and leadership abilities.

The general feeling was that PAs could be trained to perform most surgical house staff functions, ie, admit patients, take histories, perform physical examinations, write preoperative and postoperative orders at the direction of the attending surgeon, provide first or second assistance in the operating room, and assist in the management of the patient on the floors, in the recovery room, in the intensive care unit (ICU), and in the emergency room. This is how surgical PAs currently function at Norwalk Hospital.[4] The residency program was designed to provide the entering PA with the knowledge, skills, and experience to perform these functions. Emphasis is placed on understanding the pathophysiology of disease necessary for patient management.

ORDER WRITING

It was apparent early on that a key factor in the utilization of PAs as surgical house staff was closely linked to their abilities to write orders. Criteria were set up so that all orders were written at the direction of the attending surgeon and were countersigned within 24 hours. Orders written at the direction of the attending surgeon represent either the transmittal of direct orders or, as is often the case, orders that are in keeping with the pattern of care for each individual surgeon. Although permitting nonphysicians to write orders was difficult for many attending physicians in other disciplines to accept, the experience at Norwalk Hospital has indicated that it enables the surgical service to function in a manner consistent with proper patient care.

The director of the pharmacy at Norwalk Hospital reported in 1985 that "the overall quality of drug therapy orders written by PAs has proven to be generally quite good" and that "the number of orders requiring confirmation, clarification, or modification at the request of our pharmacists is comparable to those written by house staff or attending physicians." He additionally noted that "the spirit of cooperation and accessibility of the PAs has resulted in an excellent working relationship with the pharmacy staff."

OBJECTIVES

The objectives of Norwalk's PA Surgical Residency Program are simply stated: (1) to maintain excellence of surgical patient care through the use of well-trained surgical PAs who perform the functions of surgical house

Accepted for publication June 20, 1988.

From the Department of Surgery, Norwalk (Conn) Hospital (Ms Brandt and Drs Beinfield and Laffaye); Department of Surgery, Yale University School of Medicine, New Haven, Conn (Drs Beinfield and Laffaye); and Office of the Vice President, St Louis University Medical Center (Dr Baue).

Reprint requests to Norwalk/Yale PA Surgical Residency Program, Norwalk Hospital, Norwalk, CT 06856 (Ms Brandt).

officers and (2) to involve the surgical attending staff in an ongoing educational program.

STRUCTURE

The program was developed during the summer of 1976 and was initiated that September with a class of 12 PAs. The current structure encompasses a full calendar year divided into trimesters: one on rotation at Yale University School of Medicine and two on the surgical service at Norwalk Hospital. The didactic curriculum at each institution is ongoing with the clinical experience.

During the eight months at Norwalk Hospital, the curriculum consists of over 90 hours of general surgical and specialty lectures, teaching rounds, patient management problem sessions, a review of selected surgical readings, medical writing, medical ethics, and journal club. A paper suitable for publication is required. Clinically, PA residents are trained as assistants to the surgeons in the preoperative and postoperative management of patients on the floors and as first assistants in the operating room. They function as surgical house staff, taking inhouse call on nights and weekends.

The four-month Yale rotation, developed to complement the Norwalk experience, stresses the pathophysiology of surgery in three major courses: anatomy with cadaver dissection; animal surgery; and physiology. An oral research presentation is required. Clinical rotations are required in anesthesiology and emergency medicine. A choice of two electives is offered in any discipline, including burns/plastic and reconstructive surgery, orthopedics, cardiothoracic and vascular surgery, cardiology, pediatric surgery, or radiology. The strengths of both institutions, Norwalk Hospital and Yale University School of Medicine, are used to maximum advantage.

The career objectives of the PAs who enter the surgical residency also help determine the program's structure. A diverse surgical subspecialty clinical curriculum makes available all disciplines at Norwalk Hospital, Yale–New Haven Hospital, and the West Haven (Conn) Veterans Hospital. An elective rotation in cardiothoracic surgery was established at the University of Massachusetts Medical Center, Worcester. Thus, Norwalk's PA surgical residents train for specific employment opportunities while meeting the service needs of the hospital.

ADMISSIONS

A formal admissions process was developed in 1978. A committee composed of the program's directors, three general surgeons, including the department chairman, and a representative of the surgical PA staff reviews each completed application and interviews selected candidates. Applicants invited for interviews spend a full day touring both Norwalk Hospital and Yale University School of Medicine, meeting with the admissions committee and talking with members of the current class. This approach enables applicants to make a more informed choice and reinforces a "match" between candidates selected and the residency program. To date, only two of the PAs entering the residency have failed to complete the program.

As of August 1987, the PA Surgical Residency has graduated 110 surgical PAs. On average, 90% of the PAs entering the residency have at least baccalaureate degrees. Most graduated in the top 10% of their respective PA schools. Although applicant numbers fluctuated widely during the first years of the program, they currently remain fairly constant, averaging 7.5 applicants per residency position. An increase in employment of PAs in surgery, specifically as surgical house staff in hospital settings and in cardiothoracic private practice groups has been noted nationally.[5] If the market trend toward specialty employment of PAs continues, the demand for postgraduate specialty training should remain stable or experience a growth. Predicted increases in the numbers of practicing physicians has failed to impact negatively on the employment of PAs in the specialty areas.

Table 1.—Division of Total Work Time of Respondents by Surgical Work Setting*

	Mean % of Total Time (No. Reporting in Each Category)		
Category	Hospital (n=25)	Private Practice (n=19)	University Medical Center (n=6)
Clinical	79.2 (25)	83.4 (19)	84.2 (6)
Administrative	9.6 (11)	9.2 (11)	10.0 (1)
Patient education	12.6 (19)	11.6 (12)	15.0 (2)
Teaching PAs	12.3 (12)	5.5 (2)	...
Research	5.4 (5)	6.4 (5)	11.7 (3)

*PA indicates physician assistant. N = 50.

EVALUATION

The program's 11-year experience was evaluated on the basis of the following questions: (1) Have the initially stated objectives been met? (Are the PAs performing most functions of surgical house staff in a satisfactory manner and is the attending staff actively involved in a teaching program?); (2) Do the program's alumni feel that their training was worthwhile?; (3) Are the alumni satisfied with their employment and career choice?

Since 1977, the surgical service at Norwalk Hospital has continued exclusively to use surgical PAs in house staff positions. The number of permanent staff PA positions has increased from six in 1977 to 14 in 1987 due to an increase in the service needs of the institution. Of the 110 PAs who have completed the program through 1987, 35% (39) have served in the Department of Surgery at Norwalk as staff surgical PAs. Replacements for staff PA positions are always recruited from the current residency class. The average length of employment beyond the residency year as a staff PA at Norwalk is four years, but several surgical PAs remain on staff after more than ten years, providing continuity for the surgical team.

Of the 62 surgeons currently on active staff at Norwalk Hospital (excluding oral surgeons), 42 are actively involved in the didactic curriculum of the program, presenting lectures, chairing teaching conferences, and making daily bedside rounds. Additionally, 25 attending physicians from other disciplines, including medicine, cardiology, radiology, pathology, respiratory therapy, obstetrics/gynecology, and pediatrics, present lecture material in their various specialties. Five surgeons help plan the didactic curriculum, clinical evaluation methods, and tests. Staff PAs are responsible for a series of 20 lectures for student PAs who rotate on the surgical service. The team approach to patient care and education is reinforced by assigning a staff PA, a PA resident, and a student PA to each group of surgeons.

ALUMNI SURVEY

To determine the alumni's assessment of their training and to follow up their employment, a decriptive questionnaire was mailed in July 1987 to 99 physician assistants who completed the PA Surgical Residency Program. Job networking and various alumni functions enable the PA surgical residency office to maintain an up-to-date address file on most graduates. The survey was designed to obtain demographic information, as well as to determine relationships between current employment, PA surgical residency training, and job satisfaction. Seventy-seven questionnaires (77.8%) were returned. Three of these were excluded because the subjects were no longer working as PAs (one physician, one

Table 2.—Division of Clinical Work Time of Respondents by Surgical Work Setting*

Type of Work	Mean % of Clinical Time (No. Reporting in Each Category)		
	Hospital (n=25)	Private Practice (n=19)	University Medical Center (n=6)
Preoperative care	19.9 (21)	25.9 (17)	24.2 (6)
OR assistance	42.8 (23)	26.7 (18)	41.7 (6)
Postoperative care	30.0 (23)	24.3 (18)	20.8 (6)
ICU care	15.0 (13)	13.3 (8)	16.3 (4)
Emergency care	8.1 (9)	5.2 (6)	7.5 (2)

*OR indicates operating room; ICU, intensive care unit. N=50.

student, and one retired PA). Therefore, 74 responses (74.75%) were considered for this report.

RESULTS

Surgical Specialty and Setting

The survey revealed that 52 (71%) of the respondents were employed in surgical settings: 22 (30%) in general surgery; 19 (26%) in cardiothoracic and vascular surgery; eight (11%) in orthopedics; and three (4%) in other surgical subspecialties. Although 22 (29%) were employed in nonsurgical areas, nine (12%) worked in emergency medicine or trauma, where their surgical skills were used.

Hospitals (35 [47%]) and university medical centers (nine [12%]) employed 44 (59%) of these graduates, while private practice groups employed 22 (30%). The remaining eight (11%) worked in corporations, health maintenance organizations, clinics, and PA programs. Cardiothoracic and orthopedic groups employed 18 (90%) of the privately employed surgical PAs, while only seven (28%) of the hospital-based surgical PAs worked in these two specialties. Thirty-three percent (two) of the university medical center–employed respondents worked in cardiothoracic surgery; none worked in orthopedic surgery. The majority of hospital-based surgical PA respondents (17 [68%]) worked in general surgery. Ten (28.5%) hospital-employed respondents worked in nonsurgical specialties, seven of these in emergency departments.

Work Categories

Since Norwalk's training program emphasizes operative, intraoperative, and postoperative aspects of surgical patient care, division of work time by type of work was specifically asked on the questionnaire. All respondents identified as working in a surgical specialty regardless of setting spent the majority of their time performing clinical duties (Table 1). Two surgically employed respondents were excluded from these tables: one employed by a health maintenance organization and one privately employed cardiothoracic surgical PA who did not respond completely to the breakdown of work time. The tables therefore represent the responses of 50 surgical PA respondents. When broken down by specific type of work, clinical time was predominantly divided between preoperative, intraoperative, and postoperative care (Table 2). More than half of the respondents employed in surgical hospital or university medical center settings also spent time managing patients in an ICU. Slightly less than half of the privately employed surgical PAs worked in an ICU.

Whereas almost half of the hospital-employed surgical PAs teach PAs, none of the university medical center surgical PA respondents spent time in this category. Patient education occupied about 12% of the time for 76% of the hospital-based surgical PAs and 63% of the privately employed surgical PAs. One third of the surgical PAs working in university medical centers were active in patient education.

Working Hours

The questionnaire asked the average number of hours worked per week and the number of "on-call" hours. Considering only full-time respondents and including on-call hours, the survey revealed that 51 (75%) worked between 40 and 60 hours per week, six (9%) worked less than 40 hours per week and were still considered full-time employees, and 11 (16%) worked in excess of 60 hours per week. Six respondents considered part-time workers were excluded from these figures. Forty-nine (66%) took call: 34 (69%) of these from home by beeper, 15 (31%) inhospital. Of those required to take call, 30 (62%) were compensated for their on-call time: 19 (63%) of these received additional salary and 11 (37%) were given compensatory time off.

Acceptance of Orders by Nursing Staff

Writing patient orders is an important aspect of the PA Surgical Residency Program. Acceptance of these orders by the nursing staff is essential to the surgical PA's job performance. Eighty-nine percent of the survey's respondents reported that they were permitted to write orders: 79% of these stated that they never encountered difficulties with acceptance by nursing staff, 18% rarely had problems, and only 3% said that nursing staff refused to accept their orders.

Salaries

Fifty-two (77%) of the 68 responding full-time employed alumni reported annual salaries between $30 000 and $49 000; nine (13%) earned more than $50 000. These figures include all respondents working full-time regardless of length of employment. The survey indicated that most full-time and part-time respondents (70 [94.6%]) received time off and reimbursement for continuing medical education in addition to their salary and vacation time.

Value of Training

Particularly encouraging were responses to questions regarding the value of the PA surgical residency training. All respondents indicated the positive value of their surgical residency training; 98.6% indicated value to current employment (82.4% very much and 16.2% moderately so), and 1.4% reported that the training was not relevant to their current employment but was important for employment in the surgical specialties. Ninety-five percent would recommend the Norwalk/Yale PA Surgical Residency Program to PAs interested in surgery, and 95% stated that postgraduate training was important to the PA profession, particularly in the specialties.

Job Satisfaction

When asked to rate current level of job satisfaction from high to unsatisfactory, 84% of the responding alumni indicated a good to high degree of satisfaction. Ninety-one percent were always, with few exceptions, regarded by their employing physicians as professional members of the health care team.

COMMENT

Comparison with a 1981 survey by the Association of Physician Assistant Programs shows that Norwalk Hos-

pital/Yale alumni closely follow the national trend in surgical subspecialty employment. The survey lists general surgery (37.3%), orthopedics (23.6%), and cardiothoracic surgery (19.2%) as the top three surgical subspecialties.[6] Our survey indicated the same three leading employment specialties, although more respondents work in cardiothoracic surgery than orthopedics.

The survey finding that the majority of responding alumni not only valued their postgraduate surgical training but also would recommend the program to PAs interested in surgery combined with the high degree of job satisfaction and professional respect spoke well for the future of postgraduate training in the specialties. The high percentage of respondents reporting the importance of postgraduate education to the PA profession further supports the continuation of postgraduate specialty training for PAs. Survey respondents commented that formal postgraduate specialty training provided them with the "fastest way to get the broadest exposure" in surgery and the subspecialties, allowing them to build confidence and competence. Additional comments indicated the need for postgraduate training in the specialties as an option for primary care PAs to provide growth in their level of responsibility. Many respondents indicated that being well trained in surgery opened doors and expanded employment opportunities.

Division of clinical work time corresponded with the structure and emphasis of the program in the total management of the surgical patient. Most responding alumni working in surgical settings are using their skills and knowledge in the preoperative, intraoperative, and postoperative areas of care.

Salary ranges among survey respondents confirm studies that identify surgery as one of the highest paid areas of employment for PAs. Ninety percent of the responding alumni earned more than $30 000 annually, whereas a 1984 American Academy of Physician Assistants survey showed approximately 60% of PAs nationally to be earning $20 000 to $30 000 per year.[7] Reasonable working hours, including on-call time, were also reported by 74% of the respondents, dispelling fears of long "residency" hours. No doubt these factors—salary, working hours, and full use of skills—influenced the reported high degree of job satisfaction.

SUMMARY

The Norwalk Hospital/Yale University School of Medicine PA Surgical Residency Program is one solution to the increasing problem of providing adequate coverage of surgical patients in hospitals without physician surgical residents. Employment of surgeons as permanent house staff is professionally unattractive and financially prohibitive. Appropriately trained PAs are able to fulfill most house staff service requirements whether they are employed exclusively or in conjunction with physician residents. It is, however, a mistake to employ PAs as alternate house staff unless the educational and professional differences between physician residents and PAs are recognized. Unlike physician residents, surgical PAs have a limited upward mobility. Adjustments must be made to provide appropriate scheduling, compensation, and training to accommodate the surgical PA's permanent employment situation. A commitment must be made to provide surgical PAs with support, supervision, and continuing education appropriate to their profession and their function as members of the surgical team. Review of Norwalk's experience indicates that the postgraduate surgical residency for PAs has benefited both the hospital, in meeting its service and educational requirements, and the surgical PA, who enjoys an advantage in an increasingly specialized PA job market.

Invited Editorial Comment

Progressive changes in various aspects of health care provision for inpatients and outpatients are continuing to develop, and as informed health care providers we must all keep abreast of these changes and their impact on our daily activities. The article by Brandt et al describes a one-year surgical training program for PAs. While the authors emphasize the educational value of the experience, we are provided with limited objective information about the quality of the educational experience. We are told of the characteristics of subsequent employment and remuneration of individuals finishing the educational program; however, we are not informed of any educational objectives that have been accomplished. For example, how do the graduates fare on certifying and recertification examinations?

The issue of order writing by PAs remains controversial. The Joint Review Committee for Physician's Assistants approved by the American College of Surgeons indicates that PA tasks to be performed "include transmission and execution of the surgeon's orders." In the program described by Brandt et al, this is interpreted as orders written "that are in keeping with the pattern of care for each individual surgeon."

Considerable difficulty exists with defining roles, and even more difficulty exists in defining needs in the provision of health care. The PA appeared as a physician surrogate in a period of perceived physician shortages. Currently, we have no evident physician shortage but have resident physician shortages for which surgical PA programs are being advocated. Current nursing manpower needs have been highlighted by a recent decision by the American Medical Association to begin a program to train "registered care technologists" to function somewhere between nurses' aides, licensed practical nurses, registered nurses, and nurse clinicians. The tasks performed by PAs in the article by Brandt et al are in other circumstances performed by nurses. The exact role of all of these health care workers is obscure.

Physicians' assistants are not likely to remain *dependent* health care providers and neither are surgical PAs. As recently stated in *Alternatives in Health Care Delivery* (Carter RD, Perry HB [eds], St Louis, WH Green, p 312), PAs are capable of providing *interdependent* rather than physician *dependent* health care and should be accepted as being "fiscally autonomous providers." Fiscally autonomous, *interdependent* surgical physician assistants could eventually seek hospital staff and operating privileges and create another class of surgeons to replace the disappearing general practitioners that operate.

Physiologic Effects of Steep Positioning in the Surgical Intensive Care Unit

Loren D. Nelson, MD, Hans B. Anderson, RRT

• Ten hemodynamically stable patients requiring mechanical ventilation for radiographically symmetric acute lung disease were studied during steep lateral positioning and continuous rotation in a Roto Rest kinetic treatment bed. There were no significant hemodynamic or ventilatory differences among the four positions (supine, right side down, left side down, and rotating). In four patients, arterial oxygen pressure (Pa_{O_2}) decreased 16% to 49% in the lateral position when compared with the supine position. Continuous rotation restored the Pa_{O_2} toward the supine value in each patient. In six patients, Pa_{O_2} increased 11% to 35% during lateral positioning. In five of the six patients, the increase in Pa_{O_2} differed between sides, suggesting asymmetric lung disease. Continuous rotation did not significantly alter the Pa_{O_2} from the supine values in these patients. Adverse effects on oxygenation caused by positional changes may be reversed by continuous rotation using the Roto Rest kinetic bed.

(*Arch Surg* 1989;124:352-355)

Steep positional changes are commonly used in postoperative patients to help prevent pulmonary complications. These changes in position may affect pulmonary gas exchange by altering both ventilation and perfusion.[1] The alterations produced by position changes may have therapeutic implications in patients with mismatching of ventilation and perfusion. Though positional variation in pulmonary gas exchange may be more pronounced in patients with unilateral disease,[2] it may also occur in patients with radiographically symmetric disease.[3]

The Roto Rest kinetic bed has been used since before 1974 with only anecdotal reports regarding its physiologic effects. The purpose of this study is to evaluate the effects of steep positional therapy using the Roto Rest kinetic bed on pulmonary gas exchange and hemodynamics in patients with radiographically symmetric acute lung disease.

PATIENTS AND METHODS

Ten patients admitted to the surgical intensive care unit (SICU) at Jackson Memorial Medical Center, Miami, were studied. All were hemodynamically stable, had a functioning pulmonary arterial catheter, and were receiving mechanical ventilatory support for radiographically symmetric acute lung disease. The patients were awake and alert so as to be able to give informed consent. No patients were receiving inotropic support at the time of study, but three were receiving low-dose dopamine hydrochloride (<3 μg/kg/min), two were receiving intravenous aminophylline, and one was receiving sodium nitroprusside (<1 μg/kg/min; Table 1). The administration rate of these medications was unchanged during the study. The primary diagnosis at the time of admission to the SICU and initial chest roentgenographic findings are summarized in Table 1.

Measurements of intravascular pressures, cardiac output, arterial and mixed venous blood gases, oxygen consumption ($\dot{V}_{O_2}$), and carbon dioxide production ($\dot{V}_{CO_2}$) were made after 30-minute periods of stabilization in each of four positions: supine, right side down, left side down, and rotating. The order of position changes was determined by a random numbers table. Each position was achieved using the Roto Rest kinetic bed. During the rotating mode, the patient was turned from side to side through an arc of 124° approximately every 3½ minutes. The mean time required to complete the measurements was 3.7 ± 0.9 hours.

Pressure transducers were calibrated to the level of the left atrium before each measurement. During continuous rotation, pressures were measured and cardiac output injections were performed as the rotating bed crossed the horizontal position. No attempt was made to estimate intrathoracic pressure, and therefore transmural pressures were not recorded. Cardiac output was measured in triplicate by the thermodilution technique using 10 mL of room-temperature 5% dextrose in water. The $\dot{V}_{O_2}$ and $\dot{V}_{CO_2}$ values were measured by inspired and expired gas analysis using a metabolic gas monitor (MGM/TWO).

All patients were receiving mechanical ventilatory support via an artificial airway. Inspired oxygen concentration was maintained at 0.45, and positive end-expiratory pressure was titrated to achieve an arterial oxygen pressure (Pa_{O_2}) of greater than 65 mm Hg in the supine position. Mechanical tidal volume was set at 12 to 15 mL/kg. Intermittent mandatory ventilation was adjusted to keep the arterial carbon dioxide pressure (Pa_{CO_2}) between 35 and 45 mm Hg and pH greater than 7.35. Ventilator settings were not altered during the study period. Arterial and venous blood gas analysis was performed using an automated blood gas analyzer (Corning 178). Venous oxygen saturation was measured using an Oximetrix (Oximetrix-3) continuous in vivo analyzer, an American-Optical Unisat cooximeter, or an Instru-

*BSA indicates body surface area; IMV, intermittent mandatory ventilation rate (breaths per minute); PEEP, positive end-expiratory pressure (centimeters of water); ARDS, adult respiratory distress syndrome. Dopamine and sodium nitroprusside are given in micrograms per kilogram per minute, aminophylline in milligrams per hour. For all patients, fraction of inspired oxygen was 0.45.

mentation Laboratories 282 cooximeter. Derived hemodynamic and pulmonary variables were calculated using standard formulas.[4]

Serial portable chest roentgenograms were done daily while the patients remained intubated. The films were reviewed by radiologists who were unaware of the study results.

Measured and calculated variables were compared using a χ^2 analysis or paired t test. P values of less than .05 were considered to be statistically significant. This study was approved by the University of Miami Subcommittee for the Protection of Human Subjects.

RESULTS

There were no statistically significant differences in mean arterial pressure, cardiac index, central venous pressure, pulmonary artery occlusion (wedge) pressure, systemic vascular resistance, pulmonary vascular resistance, or left ventricular stroke work index during any of the four positionings (Table 2).

There were no statistically significant differences in spontaneous ventilatory rate, spontaneous tidal volume, total minute ventilation, Pa_{CO_2}, $\dot{V}_{CO_2}$, dead space–tidal volume ratio (Vd/Vt), or effective dynamic compliance among the various positions (Table 2). The Pa_{CO_2} increased more than 10% above the supine value in the lateral positions in two patients and during continuous rotation in two patients, but in no case was the increase more than 8 mm Hg. The increase in Pa_{CO_2} was due to an increase in $\dot{V}_{CO_2}$ in three instances and an increase in Vd/Vt in the fourth instance.

The Pa_{O_2} varied more than any other value studied during the positionings (Table 2 and Fig 1). In four of ten patients, Pa_{O_2} decreased by more than 10% (range, 16% to 49% [24 to 65 mm Hg]; mean decrease, 28% [46 mm Hg]) in both of the lateral positions when compared with the supine position (Fig 2). The mean supine Pa_{O_2} in these patients was 143 mm Hg and the mean lateral Pa_{O_2} was 97 mm Hg ($P<.025$). In one patient the decrease in Pa_{O_2} was associated with an increase in right-to-left physiologic shunt (Qsp/Qt), in two with an increase in $\dot{V}_{O_2}$, and in one an increase in both $\dot{V}_{O_2}$ and Qsp/Qt. Continuous rotation restored the Pa_{O_2} toward the supine value (mean, 136 mm Hg) in each of these four patients. No patient who had a significant decrease in Pa_{O_2} in the lateral positions developed asymmetric progression of infiltrates on serial chest roentgenograms.

In six of ten patients, Pa_{O_2} increased by more than 10% (range, 11% to 35% [15 to 27 mm Hg]; mean increase, 22% [21 mm Hg]; $P<.001$) in one lateral position compared with supine (Fig 3). In five of these six patients, the increase in Pa_{O_2} differed between the two lateral positions by more than 10% (range, 11% to 33% [17 to 27 mm Hg]; mean difference, 24% [22 mm Hg]), suggesting asymmetric lung disease. Three of these five patients later developed asymmetric progression of their pulmonary infiltrates on serial chest roentgenograms. The increase in Pa_{O_2} was associated with a decrease in Qsp/Qt in four patients. In the other two patients the increase in Pa_{O_2} was not associated with a decrease in Qsp/Qt or $\dot{V}_{O_2}$, or an increase in mixed venous oxygen saturation. Continuous rotation through the entire 124° arc did not significantly alter the Pa_{O_2} from the supine values in patients whose Pa_{O_2} increased in the steep lateral positions ($P>.05$).

COMMENT

A major cause of arterial hypoxemia is mismatching of ventilation and perfusion.[1] Both ventilation and perfusion, to some degree, depend on patient position. Since the normal perfusion pressure of the pulmonary circulation is low and the relative hydrostatic pressure differences due to gravity are high (especially in the upright position), changes in the distribution of blood flow occur with position changes. There is also a redistribution of ventilation with position changes. However, the changes in the distribution

of perfusion are greater than the changes in regional ventilation. Since relative matching of ventilation and perfusion is required for optimal gas exchange (especially oxygenation), position changes may have a major effect on

Fig 2.—Decreases in arterial oxygen pressure (Pa_{O_2}) during steep lateral positioning (seen in four patients) were corrected during continuous rotation therapy.

Fig 3.—Increases in arterial oxygen pressure (Pa_{O_2}) during steep lateral positioning (seen in six patients) were less than decreases noted in Fig 2. Continuous rotation in these patients did not alter Pa_{O_2} from supine values. ASYM indicates three patients who later developed asymmetric infiltrates on chest roentgenograms.

arterial oxygenation. This is especially true in situations where normal compensatory mechanisms are impaired.

Unilateral pulmonary disease is a situation where lateral positioning has been shown to have major effects on oxygenation.[2,3,5-7] However, differences in oxygenation produced by position changes also occur in patients with radiographically symmetric pulmonary disease.[3] In patients with no evidence of acute pulmonary disease, the effect of positional changes on oxygenation is minimal.[3]

Frequent position changes and early ambulation of postoperative patients have long been the standard of care to prevent pulmonary complications. Patients who are confined to bed because of injuries or critical illness have been difficult to manage and have a high incidence of pulmonary complications. Use of the Roto Rest kinetic treatment bed has been advocated as a means to minimize problems related to immobility.

The Roto Rest bed has been shown to be effective in improving oxygenation in patients with acute unilateral pulmonary injury.[8] This study was performed to evaluate the effect of steep lateral positioning and continuous rotation between lateral positions on hemodynamics and

gas exchange in critically ill patients with radiographically symmetric acute pulmonary disease.

We found no significant effect of steep lateral positioning or continuous rotation on cardiac index, arterial blood pressure, pulmonary arterial pressure, central venous pressure, pulmonary arterial occlusion (wedge) pressure, or the derived parameters of systemic and pulmonary vascular resistance and ventricular work. Though these patients were preselected to be hemodynamically stable and were not receiving significant inotropic or vasopressor support, their status, at some point in their SICU admission, was in sufficient question to warrant placement of a pulmonary artery catheter. These findings are significant in that kinetic therapy has in the past been withheld for fear of precipitating adverse hemodynamic effects. Adverse hemodynamic effects were not seen in any patient in this study.

We also found no significant effects on total ventilation; ie, there were no statistically significant changes in Pa_{CO_2} or the direct determinants of Pa_{CO_2} ($\dot{V}_{CO_2}$, alveolar ventilation, ventilatory rate, minute ventilation, tidal volume, or Vd/Vt). We cannot say from this study whether there were effects on regional ventilation of the lung or atelectasis.

The major effect of short-term steep positional and kinetic therapy was on oxygenation. In four patients, Pa_{O_2} decreased 16% to 49% in one of the lateral positions. The decreases in Pa_{O_2} were not predictable from radiographic data. Continuous rotation restored the Pa_{O_2} toward the supine value in all four patients. This suggests that in patients who require position changes but develop hypoxemia in the lateral position, kinetic therapy has a good chance of improving the hypoxemia.

On the other hand, six of ten patients demonstrated an increase in Pa_{O_2} in the lateral position, and five of these six patients had a difference in Pa_{O_2} between the lateral positions, suggesting asymmetric lung disease. Three of these five patients later demonstrated asymmetric lung disease on serial chest radiographs. In these patients there was no significant difference in oxygenation between rotating and supine positions. However, if these findings are substantiated in a larger series, the Roto Rest may prove to be useful in predicting which patients may develop asymmetric lung disease and in treating hypoxemia resulting from asymmetric lung disease.

The differences in Pa_{O_2} between supine and lateral positions were associated with a change in Qsp/Qt in six of the ten patients. In two patients whose Pa_{O_2} decreased in the lateral position, the decrease was at least partially explained by an increase in $\dot{V}_{O_2}$ rather than changes in the distribution of pulmonary blood flow. In two patients whose Pa_{O_2} increased in the lateral positions, the increase could not be explained by changes in the common determinants of Pa_{O_2}: cardiac output, Qsp/Qt, mixed venous oxygen saturation, or $\dot{V}_{O_2}$.

This study has addressed only the immediate, short-term effects of positional therapy on hemodynamics and pulmonary function. Whether or not the effects noted in this study will be substantiated by larger studies and whether the effects on oxygenation will be of lasting clinical or therapeutic significance remains to be seen. It is conceivable that the effects on oxygenation may become more pronounced over time, but it is also possible that these effects may be negated by adaptive physiologic changes or additional pathologic insults.

We express our thanks to the nurses and staff of the SICU for their support in completing this study.

The Effect of Digital Rectal Examination on Serum Levels of Prostatic-Specific Antigen

Michael K. Brawer, MD; Ron B. Schifman, MD;
Frederick R. Ahmann, MD; Marie E. Ahmann; Karen M. Coulis

Serum prostate-specific antigen (PSA) and acid phosphatase (AP) levels were measured before and after digital rectal examination in 26 patients with varying genitourinary complaints. Prostate examination had no effect on the level of these markers. However, AP levels demonstrated greater within-day, intraindividual variance than PSA levels. Digital rectal examination does not appear to be a source of preanalytical error for serum PSA or AP determinations (*Arch Pathol Lab Med* 1988;112:1110-1112).

Nosocomial Abscess

Results of an Eight-Year Prospective Study of 32 284 Operations

Mary M. Olson, RN, BSN, Melody O'Connor Allen, MD

• This article details the results of 114 abscesses found after 32 284 operations during a 30-day prospective infection surveillance. Abscesses occurred more often after gastric/esophageal (3.6%), colonic/appendiceal (2.8%), and pancreatic/biliary (1.5%) operations. Abscesses were intra-abdominal (58%), pelvic/perineal (31%), and retroperitoneal (3%). The most common pathogens were *Escherichia coli*, enterococci, and *Bacteroides* organisms. Abscess symptoms appeared 10 ± 6 days (mean ± SEM) after surgery and were drained 8 ± 8 days after onset of symptoms. Hospital stay from onset of symptoms to discharge was four times greater than that for wound infection. Twenty-seven patients (28%) died. Mortality was increased in patients older than 50 years and in those with renal failure or multiple abscesses. Nosocomial abscesses had a greater morbidity than wound infection. Excessive expense and high mortality warrant infection surveillance for both wound infection and ongoing nosocomial abscesses. (*Arch Surg* 1989;124:356-361)

Prospective infection surveillance is an established means of ensuring early identification and treatment of postoperative wound infections.[1-6] Surveillance at our institution resulted in a steady decline in overall wound infection rates with significant reduction in the number of infection-related hospital days and costs.[1] Knowing that the rates of morbidity and mortality of postoperative abscess far exceed those of simple wound infection,[5,7] we undertook to assess the value of infection surveillance as a means of reducing hospital costs related to nosocomial abscess. We describe herein our eight-year experience with prospective surveillance of over 30 000 operations for postoperative abscesses. Clinical factors associated with high risk of death from abscess were sought. The impact of infection surveillance on time to diagnosis and incidence of wound infection and nosocomial abscess were determined by comparing results during each year of surveillance with the year in which surveillance was initiated (1977).

PATIENTS AND METHODS

Data Collection

Postoperative infection surveillance was carried out by one of us (M.M.O.), a nurse epidemiologist, after 32 284 operations performed at the Minneapolis Veterans Administration Medical Center from 1977 to 1985. Patients with wound infections and abscesses were identified during daily visits to surgical wards and by monitoring all culture results. A wound was considered clearly infected if pus discharged from it. Wounds with serous or nonpurulent drainage and negative cultures were considered infected only if significant physical signs of sepsis were present concurrently (warmth, erythema, induration, and pain) and if infection was diagnosed medically. Wounds with cellulitis and no drainage and suture abscesses were not considered as being infected. *Postoperative abscesses* were defined as any circumscribed assemblance of pus defined at operation, during percutaneous drainage, or at autopsy, or when the abscess cavity was clearly demonstrated on contrast roentgenography. Only those abscesses noted within 30 days of initial operation that were *not* present at that operation were included in the study.

Operations were classified as clean, clean-contaminated, or contaminated according to criteria established by the American College of Surgeons.[8] Clinical data were collected regarding the initial and all subsequent operations. Specific data were collected regarding methods of detection, type, and results of treatment of abscesses. *Mortality* was defined as death occurring during this hospital admission. One patient was discharged and readmitted, and death occurred within 30 days of the initial surgery.

Data Analysis

Clinical variables prior to initial operation, operative data, and postoperative course were compared between survivors and nonsurvivors. Comparisons were performed using Student's *t* test and Fischer's exact test, χ^2 analysis, or comparison of two percentages based on large samples when groups were appropriately large.[9] Results for all years during infection surveillance (1978 through 1984) were compared with those from the first year of surveillance (1977).

Cost Analysis

Costs related to the complication of nosocomial abscess occurring after operation were estimated for each year of the study. Estimates of cost per wound infection were calculated using an average increase of ten hospital days per patient with infection.[2] Estimates of cost per abscess were calculated using an average increase of 44 hospital days per patient based on abscess data obtained from the present study. Minnesota Hospital Association estimates of cost per day were used (estimates published yearly in *Minneapolis Star Tribune*).

RESULTS

Demographic Data

Ninety-seven patients (92 men and two women) developed 114 abscesses during the eight-year study period.

Accepted for publication Nov 4, 1987.

From the Department of Surgery (112), Veterans Administration Medical Center, Minneapolis.

Reprint requests to Department of Surgery (112), Veterans Administration Medical Center, 54th Street and 48th Avenue S, Minneapolis, MN 55417 (Ms Olson).

The majority of abscesses occurred in patients older than 50 years, with a mean (±SEM) age of 60±15 years (Fig 1). Fifty-seven percent of patients had a history of cancer, 24% were alcoholic, 17% were diabetic, and 8% had undergone either radiotherapy or chemotherapy. At the time of initial operation, four patients had respiratory failure, 12 had renal failure, and three had shock.

Initial Operation

The median duration of hospitalization prior to initial operation was ten days, with a range from zero to 71 days. Ninety percent (87/97) of patients received preoperative antibiotics. Of these patients, 68% received a cephalosporin within four hours of operation, while the remaining patients received oral neomycin sulfate plus erythromycin stearate (36%), an aminoglycoside (29%), ampicillin sodium (13%), or clindamycin phosphate (13%). The largest number of abscesses occurred on the general surgery services (71 of 97). Nearly one third of all abscesses occurred after colonic or rectal surgery, followed next in frequency by gastric, pancreatic/biliary, and urologic surgery (Fig 2).

Ten percent of operations in 97 patients who developed nosocomial abscess were classified as clean, 57% as clean-contaminated, and 33% as contaminated. The majority of operations were elective (78%). Wound closure following operation was primary in 88% of patients. Drains were inserted in 26 of 97 patients at the initial operation.

The number of wound infections and abscesses in different wound classes were compared (Table 1). The highest incidence of abscess formation (1.0%) comprised 32 of 3251 operations in the contaminated classification.

Infectious Complications Other Than Abscess After Initial Operation

Infectious complications other than abscess occurred in 56 of 97 patients. In 38 patients, this "other site" infection had the same pathogen as the abscess. The most common type of infection was bacteremia (24%). Eleven patients (11%) had wound infections compared with an overall wound infection rate of 2.5% in 32 284 patients who underwent operations during the study period. Wound dehiscence occurred in 10% of patients with abscess, the median day of dehiscence being postoperative day 6 (range, three to 12 days). Pneumonia and urinary tract infection occurred in 11% of patients.

Abscess Data

The majority of abscesses were located in the abdominal cavity (58%), with 31% in the perineum or pelvis and 3% in the retroperitoneum (Table 2). The median time from initial operation to clinical presentation of all 114 abscesses was eight days (range, three to 29 days). The incidence of wound infection and nosocomial abscess by type of operation was calculated for the eight-year study period (Table 3). Signs and symptoms of abscess formation included a white blood cell count greater than 10×10^9/L (81%), a temperature greater than 37.8°C (78%), localized pain and tenderness (61%), ileus (38%), diarrhea (33%), abdominal distention (27%), nausea and vomiting (23%), bacteremia (24%), confusion (13%), palpable mass (8%), and shock (7%). *Bacteroides* bacteremia occurred in 13 patients. Renal failure following surgery was present in 13% and respiratory failure in 10% of patients. Radiographic data obtained in patients with abscess were presented as the number of abnormal findings (ie, diagnostic of abscess) out of the total number of studies performed on the 97 patients (Table 4).

Fig 1.—Number of nosocomial abscesses by decade of life in 97 patients. Shaded bars indicate deaths.

Fig 2.—Distribution of abscesses by type of operation in 97 patients.

Ninety patients underwent drainage of abscess. Twenty-nine of the patients whose abscesses required drainage had anastomotic leaks. Three patients had small abscesses adjacent to an anastomotic leak; these abscesses were not drained. Four patients died before drainage could be performed. Seventy-three patients had one operation for drainage, 11 patients had two operations, five patients had three operations, and one patient had four operations. Percutaneous computed tomographic (CT)–guided abscess drainage was the primary procedure performed in three patients. One patient first underwent operative drainage and then repeated drainage via the percutaneous method. All patients were treated with antibiotics, which were given from two to 110 days (median, 16 days) after clinical presentation of abscess. Eighty-eight percent of patients received an aminoglycoside, while 55% received ampicillin and clindamycin, and 49% received cephalosporin. "Triple antibiotics" (ampicillin, clindamycin, and aminoglycoside) were used in 34 of the 97 patients.

The median time from presentation of abscess symptoms to drainage was four days (range, zero to 43 days). Drainage was performed from four to 50 days (median, 14 days) after the initial operation. Of the 90 patients in whom abscesses were drained, nine patients underwent the drainage pro-

Table 1.—Number of Wound Infections and Abscesses Occurring After All Operations Performed During Infection Surveillance

Wound Class*	No. of Operations	No. (%) of Patients With Wound Infection	No. (%) of Patients With Abscess
Clean	20 162	280 (1.4)	10 (0.05)
Clean-contaminated	8871	252 (2.8)	55 (0.6)
Contaminated	3251	278 (8.6)	32 (1.0)
Total	**32 284**	**810** (2.5)	**97** (0.3)

*Classification according to criteria established by the American College of Surgeons.[8]

cedure on the same day as clinical presentation. The longest time span from presentation to drainage was 43 days in one patient with a pericardial abscess. The median number of hospital days from original operation to onset of nosocomial abscess symptoms and the median number of days from onset of symptoms to the time of abscess drainage were calculated (Table 5). While there was a trend toward decreasing time from onset of symptoms to drainage of nosocomial abscess, no statistically significant differences were noted.

Cultures

Cultures of abscess fluid were obtained in 90 patients, and the following positive cultures were obtained in 88 of these patients:

Escherichia coli	34
Enterococci	34
Bacteroides	28
Klebsiella	17
Pseudomonas aeruginosa	15
Yeast	13
Anaerobic gram-positive cocci (unidentified)	12
Enterobacter	11
α-Hemolytic streptococci	11
Serratia	10
Proteus	7
Clostridium perfringens	5
Staphylococcus epidermidis	4
Clostridium species	4
Citrobacter	4
β-Hemolytic streptococci	3
Fusobacterium	2
Anaerobic gram-positive bacilli (unidentified)	1
Anaerobic gram-negative bacilli (unidentified)	1
Eubacterium	1
Acinetobacter anitratum	1
Neisseria	1
S aureus	1

The most common pathogens were *E coli*, enterococci, and *Bacteroides* organisms. In the 24 patients who had a single pathogen in pure culture, *E coli* and *P aeruginosa* were found most often. *Staphylococcus epidermidis*, α-hemolytic streptococci, and diptheroids were not considered pathogens unless they were found in pure culture.[10] Fifty-eight percent of abscesses contained only aerobes, while 9% contained only anaerobes and 33% contained a mixture of both types (Fig 3). Pathogens were sensitive to preoperative antibiotics in 50% of cases. Pathogens resistant to all aminoglycosides except amikacin sulfate were present in 9% of cultures.

Mortality

Twenty-seven (28%) of 97 patients died. The vast majority of deaths occurred in patients older than 50 years (Fig 1). Total hospital stay until death ranged from 11 to 212 days (median, 34 days). Time from drainage to death ranged from one to 160 days (median, ten days). The most common cause of death was sepsis (21 of 27 patients). Each of the remaining six deaths was due to cardiac arrest, pulmonary embolus, cancer, thrombosis of the superior mesenteric artery, massive gastrointestinal tract bleeding, or an unknown cause. Persistent abscesses were present in 11 (41%) of 13 patients at autopsy. New abscesses were found in two patients who died.

Evaluation of *preoperative clinical data* showed that prolonged prothrombin time (>13 s), renal failure, and age greater than 50 years were more common in patients who died ($P<.01$). Alcoholism, diabetes, cancer, radiation treatment, shock, respiratory failure, and abnormal values of white blood cell count ($>10\times10^9$/L), bilirubin (>21 μmol/L), albumin (<30 g/L), and hemoglobin (<75 g/L) were not common variables in patients who died. Evaluation of *operative data* failed to reveal any variable that was more common among patients who died. The variables studied included blood loss of greater than 2000/cm³, emergent operation, gross fecal soilage, unprepared bowel, and duration of operation of greater than four hours.

Original operation to onset of symptoms	7	7	9	5	11	7	7	10
Onset of symptoms to abscess drainage	6	3	4	4	4	3	6	1

*Values in parentheses indicate number of patients with abscesses.
†First year of institution of prospective infection surveillance.

In the *postoperative data*, multiple abscess, renal and respiratory failure, urinary tract and respiratory tract infection, and peritonitis were more common in patients who died ($P<.05$). Factors not significantly different between survivors and nonsurvivors were bacteremia, wound infection or dehiscence, number of drainage procedures, number of days from onset of symptoms to drainage, and recurrent abscess.

Cost Analysis

A significant decline in incidence of wound infection during the seven-year period of infection surveillance was noted when compared with the 1977 incidence (Table 6). While the incidence of nosocomial abscess formation was less than or equal to the 1977 incidence in six of seven years of infection surveillance, the incidence of nosocomial abscess was significantly lower ($P<.01$) compared with that of the first year of surveillance in only one of the years studied (1982). The mean (±SEM) time from onset of abscess symptoms to discharge was 44±32 days.

The cost related to abscess was also evaluated (Table 7). Data were calculated on the assumption that all hospital days subsequent to onset of symptoms of abscess were complication related. Cost per abscess was $13 354, while the minimal cost per patient for wound infection was $3085.[1] The number of abscesses (97) was one eighth that of wound infections (810), but the cost was at least one half less ($1 295 316 vs $2 498 750).

COMMENT

Classic articles dealing with the subject of abscess combine results of patients having primary abscess with those of patients who develop abscesses after surgical procedures, ie, nosocomial abscesses.[5,11,12] Authors quote overall mortalities from 20% to 40%, noting that patients with postoperative abscess frequently require multiple operations, have prolonged hospital stays, and have the highest risk of death. In a five-year prospective study, Krukowski et al[13] described a 0.8% incidence of intra-abdominal sepsis after abdominal operation but made no comment as to mortality or morbidity specific to that complication. The purpose of the present study was to

describe morbidity and mortality of nosocomial abscesses and to assess the value of prospective infection surveillance as a means of minimizing the incidence of this complication.

One hundred fourteen nosocomial abscesses were detected in 97 patients during an eight-year period of prospective infection surveillance after 32 284 operations. Abscesses occurred most frequently in elderly patients with multiple medical problems. The highest incidence of nosocomial abscess was in patients with contaminated operations (1%). It is pertinent to note that our method of classification includes "dirty" class IV operations[8] in the contaminated classification. Our results compare favorably with those of Krukowski et al,[13] who reported a rate of 3.8% for patients with either contaminated or dirty operations.

The majority of nosocomial abscesses were located in the abdominal cavity or pelvis (89%), while only 3% were located in the retroperitoneum. Our data are consistent with those of Hinsdale and Jaffe,[14] who described 87 patients who underwent reoperations for abdominal sepsis; the authors found that 45 of 47 nosocomial abscesses were intraperitoneal. Our results differ from studies that include primary abscesses, in which nearly one third of abscesses were located in the retroperitoneum.[12] The majority of nosocomial abscesses occur after operations on the gastrointestinal tract.[13,15,16] In our study the highest rate of abscess occurred after pancreatic operations (6%), followed by esophageal (5%), colonic (3%), and gastric (3%) operations.

The diagnosis of nosocomial abscess was made using a combination of clinical (leukocytosis, fever, and pain) and radiologic findings. The most accurate radiologic tests for diagnosing abdominal abscesses were CT (79%) and gallium (74%) scanning. When a draining sinus tract was present, the sinogram was uniformly successful in diagnosing abscess. As in other studies, CT scanning was the most useful diagnostic test for pelvic and perineal abscesses.[16-18] These data are consistent with those of Saini et al,[16] who described a 92% diagnostic accuracy with CT scanning, 77% with ultrasonography, and 75% with gallium scanning in a series of 100 consecutive abscesses.

Ninety of 97 patients in our study underwent operative drainage of abscess; of these patients 17 required more than one drainage procedure. Percutaneous CT-guided drainage was used as the primary procedure in only three patients. Several recent articles have demonstrated excellent results with percutaneous drainage of single, uncomplicated abscesses.[19-21] We anticipate more frequent use of this technique in carefully selected cases.

Death occurred in 28% of our patients, most often due to continued sepsis. Mortality was significantly associated with age greater than 50 years, preoperative renal failure or prolonged prothrombin time, multiple abscesses, postoperative renal or respiratory failure, postoperative peritonitis, and urinary or respiratory tract infection ($P<.05$). These findings are consistent with those of other authors who have found increasing age, delay in diagnosis, organ failure, generalized peritonitis, and multiple or recurrent abscess to be highly associated with mortality.[5,14-16]

The high cost of surgical complications has been well documented.[22-24] In a one-year prospective survey to identify adverse outcomes of surgery, Couch et al[22] determined a cost of nearly $50 000 per patient in whom significant mishap occurred. They concluded that continuous monitoring of surgical results would help to identify the prevalence of avoidable complications and to potentially minimize their incidence. In our institution, prospective infection surveillance clearly correlated with early detection and a steady decline in yearly incidence of wound infection during the eight-year study period. During the same period, however,

there was no significant decrease in occurrence or time to diagnosis of nosocomial abscess. We feel that the decline in wound infection rates was related not only to institution of infection surveillance, but also to several improvements in operative procedures made during the period.[1] Notably, better bowel preparation technique for colonic surgery and modification in choice of perioperative antibiotics, suggested by the work of Condon et al,[25] contributed to diminished wound infection rates. Our failure to note a concomitant decline in incidence of nosocomial abscess in these patients suggests that technical factors related to anastomotic healing are critical determinants in the development of this postoperative complication.

Nosocomial abscess significantly lengthened hospital stay, resulting in the need for operative drainage in the majority of patients, and led to abscess-related hospital costs of over $1 million. While infection surveillance by a nurse epidemiologist failed to significantly shorten time to diagnosis or time from onset of symptoms to abscess drainage, we feel that such surveillance helps to identify adverse institutional trends and lapses in technique that might otherwise go unnoticed. Most important, the surgeon must recognize that the signs and symptoms of nosocomial abscess are often subtle. A high level of suspicion must be maintained in high-risk patients to identify and to treat nosocomial abscess as rapidly as possible.

ARCHIVES OF INTERNAL MEDICINE

Prevention of Amphotericin B–Induced Renal Impairment: A Review on the Use of Sodium Supplementation

Robert A. Branch, MD

Amphotericin B is the treatment of choice for most deep-seated mycoses; however, doses may have to be limited because of concern over adverse effects such as nephrotoxicity. Evolving evidence suggests that the extent of amphotericin B–induced renal impairment may be modified via alteration of a normal physiologic feedback response that further contributes to changes due to direct nephrotoxicity. As such, renal impairment has a substantial theoretically preventable and reversible element. In animals exposed to amphotericin B, sodium loading interferes with this response. Mounting clinical evidence also supports the usefulness of sodium supplementation to prevent as well as to reverse amphotericin B–induced nephrotoxicity. At this time, the use of sodium supplementation (eg, intravenous saline and/or ticarcillin disodium, which contains 5.2 mEq of sodium per gram of drug) along with avoiding dehydration appears to be a safe and effective means of reducing the risk of nephrotoxicity associated with amphotericin B administration; however, it is not known whether renal changes can be entirely prevented. These preliminary observations merit confirmation in a prospective, randomized clinical trial (*Arch Intern Med* 1988;148:2389-2394).

Determinants of Urea Nitrogen Production in Sepsis

Muscle Catabolism, Total Parenteral Nutrition, and Hepatic Clearance of Amino Acids

Mauro Pittiruti, MD; John H. Siegel, MD; Gabriele Sganga, MD; Bill Coleman; Charles E. Wiles III, MD; Robert Placko

• The major determinants of urea production were investigated in 26 patients with multiple trauma (300 studies). The body clearances (CLRs) of ten amino acids (AAs) were estimated as a ratio of muscle-released AAs plus total parenteral nutrition–infused AAs to their extracellular pool. While clinically septic trauma (ST) patients without multiple-organ failure syndrome (MOFS) had a higher level of urea nitrogen production (25.6±13.4 g of N per day) compared with nonseptic trauma (NST) patients (14±7.5 g of N per day) and with ST patients with MOFS (4.28±1.5 g of N per day), in all groups urea N production was found to be a function of muscle protein degradation (catabolism), total parenteral nutrition–administered AAs, and the ratio between leucine CLR and tyrosine CLR (L/T) (r^2=.82, P<.0001). Since tyrosine is cleared almost exclusively by the liver, the L/T ratio may be regarded as an index of hepatic function. The significant differences between urea N production in ST and NST patients lay in an increased positive dependence on muscle catabolism and increased negative correlation with L/T in the ST group. At any L/T ratio, urea N production was increased in ST patients over NST patients, but in ST patients with MOFS, it fell to or below levels of NST patients. These data show that the ST process is associated with enhancement of ureagenesis, due to increased hepatic CLR of both exogenous and endogenous AAs. In sepsis with MOFS, a marked inhibition of urea synthesis occurs, partially explained by a decreased hepatic CLR of non-branched-chain AAs.

(*Arch Surg* 1989;124:362-372)

The physiologic response to injury is characterized by a net loss of body nitrogen, as evidenced by the increased urinary excretion of N primarily in the form of urea. It has been shown that the main source of this N loss is from the skeletal muscle[1] due to the effect of mediators released in response to injury,[2] to the altered hormonal milieu,[3,4] and to the direct effect of injury on muscle metabolism.[5,6] This muscle proteolysis is associated with an increased release of amino acids (AAs) into the plasma; these AAs appear to be then utilized by liver and other tissues,[7] either for protein synthesis,[8,9] or for oxidative catabolism. However, regardless of the catabolic pathway, the ammonia N is detoxified through synthesis of urea; thus, ureagenesis is increased. When sepsis occurs after major trauma, proteolysis is enhanced in skeletal muscle[7,8] and lipogenesis and gluconeogenesis from the deaminated AAs released are increased in the liver,[10,11] leading to a generalized protein depletion, with a state of acute protein malnutrition.[5] While muscle proteolysis cannot be totally inhibited by the administration of intravenous AA solutions, there is evidence that partial or complete N balance can be achieved.[12] However, a significant portion of the AAs infused will be catabolized in the liver, along with those AAs already available from proteolysis. As a result, there is increased N to be disposed of as urea.

Previous studies of sepsis suggest that as septic severity progresses, there is a relative impairment of hepatic function,[13] which may lead to overt liver failure in the multiple-organ failure syndrome (MOFS). This liver failure is associated with a decrease in clearance (CLR) of those AAs utilized by the liver.[14] When this happens, many of the synthetic processes that occur in the hepatocytes may be compromised, including urea synthesis. The present study is an investigation of the relative influence of muscle protein degradation and the AA CLRs as major determinants of urea production (as estimated by urea N excretion) after multiple trauma, and its modulation by posttraumatic sepsis and septic MOFS with a hepatic component.

PATIENTS AND METHODS

Patients

Urea production, muscle protein degradation (catabolism), and the body CLR of ten AAs were estimated in 26 patients with

ISS	20 ± 10.4	23.3 ± 8.9

*BSA indicates body surface area; ISS, Injury Severity Score.

multiple trauma (300 studies) who were receiving intravenous support without oral intake before and during total parenteral nutrition (TPN). The detailed clinical characteristics of this patient population have been presented previously.[15] All but three of the nonseptic trauma (NST) group and all but two of the septic trauma (ST) group were patients with multiple trauma secondary to motor vehicle accidents. The rest had major single-system injuries. The mean values for the two groups with regard to age, body weight, body surface area, and Injury Severity Score are shown in Table 1. No statistically significant differences could be found between the ST group and the NST group.

Sixteen of the 26 posttrauma patients had clinical courses uncomplicated by any septic episode or by renal failure; two patients in the NST group died (one of brain death and one following a cardiorespiratory arrest). Ten of the 26 posttrauma patients developed clinical sepsis according to the following criteria: (1) intra-abdominal purulent collection, which required drainage; or (2) severe extra-abdominal infection with positive blood cultures and systemic physiologic involvement, as demonstrated by persistent hyperpyrexia and a hyperdynamic cardiovascular response associated with low vascular resistance and increased oxygen consumption typical of the septic A state.[16]

In this group, sepsis developed between days 3 and 8 following injury. In 94% of the cases, it was evident by day 6. Seven of these patients survived the ST process. Three patients died: all of them developed progressive, overwhelming sepsis with MOFS, as defined by evidence of two or more organ failures (lung, liver, kidney, cardiac, or coagulation system), according to the criteria of Faist et al.[17] Using conventional clinical and biochemical criteria, all of these ST patients with MOFS showed some evidence of hepatocellular dysfunction during their clinical course. Renal failure (serum creatinine level, >2 μmol/L) developed late in three ST patients, in two ST nonsurvivors, and in one ST survivor. Studies during renal failure have not been included in the present analysis. All patients were in a state of good health before their injury, with the exception of one patient (a 16-year-old male), who had chronic cystic fibrosis, including cirrhotic changes. This patient underwent a splenectomy for a traumatic splenic rupture in the postinjury period: he became septic and later died of MOFS.

Serial studies of the biochemical and physiologic variables described below were begun on each patient on the day of trauma, or on the first day after trauma, and were continued on an eight-hour basis. All patients were given TPN (10% to 25% glucose solution containing 4.3% AAs). Studies were continued until TPN support was discontinued and oral feeding was started, or until death. During each eight-hour study period, several data were collected simultaneously (plasma and urine levels of AAs, urea, and 3-methylhistidine [3MH]; cardiac output and oxygen consumption by thermodilution and/or indocyanine green dilution; blood gas levels; renal CLR of urea and creatinine; hematologic and coagulation measurements; plasma levels of acute-phase-response proteins; and standard biochemical measurements). The results of the analysis of other aspects of these data are presented in detail in other communications.[14,15]

In the data analysis, the clinical course of each patient, either ST or NST, was divided into two periods: (1) early (less than or equal to five days after injury) and (2) late (more than five days after injury). Since in most patients of the ST group, sepsis became clinically evident between the fourth and sixth days after trauma, "early sepsis" roughly corresponds to the latent, preclinical, or very early phase of the ST process, while "late sepsis" identifies the clinically overt ST state. The rationale for this time-related subdivision has also been confirmed by the previous analyses of data collected from this patient population.[15]

Fig 1.—Dependence of urinary urea nitrogen (N) production on estimated muscle loss in clinically septic trauma (CST) vs nonseptic trauma (NST) patients. **Urinary Urea (g N/d) = 0.111 (Muscle Loss) + 0.073 (Muscle Loss × Sepsis) + 3.48.** n = 166; r^2 = .47; $F(2,163) = 72.3$; and $P < .0001$. Range of normal from literature (dotted box). Difference between CST and NST slopes significant by Scheffé S method ($P < .0001$). Muscle catabolism (grams per day) equals urinary 3-methylhistidine (micromoles per day) divided by 4.2.

Biochemical Methods

The separation and estimation of free AAs in plasma and 3MH in urine was carried out after deproteinization, using an AA analyzer (Beckman 6300). The estimation of urea N, creatinine, and glucose in blood and urine was performed on an analyzer (Beckman Astra-4, Beckman Instruments, Anaheim, Calif).

Urea Production

In our patient population, renal function was normal in all studies considered; urea production was estimated by the measurement of urea N excretion in the urine during each eight-hour study period. The rate of urea excretion may differ from the rate of urea synthesis for several reasons[18]: (1) renal excretion may be impaired due to prerenal causes or to renal disease; (2) a minor proportion of urea may diffuse through the body water compartments, and its excretion may be delayed, especially when sudden changes in the urea synthesis rate take place, but the studies of Long et al[19] with labeled urea indicate that in ST patients, the breakdown and recycling of urea is negligible.

Muscle Protein Degradation (Catabolism)

The amount of skeletal muscle protein degradation during each study period was estimated by the measurement of the urinary excretion of 3MH, according to the method developed by Bilmazes and coworkers.[20] The validity of this assumption has been recently questioned, since experiments performed in the rat show that a significant amount of urinary 3MH may originate from tissues other than the skeletal muscle, such as smooth muscle of the gastrointestinal tract.[21,22] However, the gut origin of a major fraction of 3MH in the rat has been challenged,[23] and the applicability of these rat data to human studies has been recently criticized.[24,25]

The use of the 3MH method to estimate human muscle protein degradation (ie, muscle catabolism) has been shown in other studies on critically ill patients to give results physiologically compatible with data obtained with more invasive techniques.[26] Also, in the human, no more than 60 μmol/d of the urinary 3MH appear to be of nonskeletal muscle origin[27] (or <15% of our mean

total of 413 μmol/d in ST patients). Even if the proportion of 3MH coming from nonskeletal muscle was quantitatively of importance, this would not interfere with the main objective of our study, which is to correlate the amount of AA released from muscle protein degradation to the rate of urea synthesis. Since actin and myosin in skeletal muscle and smooth muscle have comparable AA compositions,[28] we can expect the same qualitative uptake of plasma AAs by the liver, independently of the type of muscle from which they were released.

AA CLR

The body CLR of ten AAs (leucine, isoleucine, valine, alanine [ALA], methionine, proline, phenylalanine, tyrosine, asparagine plus aspartate, and glutamine plus glutamate [GLUT]) was estimated as a ratio of muscle-released AAs plus TPN-infused AA to the size of their extracellular pool, estimated from the plasma AA levels, according to the method that has been previously presented.[14] This computation of AA CLR is an estimate of the total-body CLR, which differs from the estimate proposed by Clowes et al,[7,12] which relies on the leg arteriovenous difference of AA multiplied by the estimated ratio of leg blood flow to total cardiac output. Nevertheless, the striking finding of these data is that there is virtually no difference in the estimated magnitude of effect, or in the nature of the responses, where they can be compared, between our data[14] and those of Loda et al[29] and Clowes and his associates.[30]

Statistical Methods

Statistical analyses were by means of linear regression analysis, and interpretation was as previously outlined.[31] The Scheffé S method[32] was used to test simultaneously the significance of any differences between regression coefficients and the differences between the pairs of regression coefficients characterizing the ST and NST groups.

The bar diagrams shown in the two figures illustrate the working out of such equations for a "typical" patient who just happened to have all of the average values for his group of each of the independent variables. The quantity of the dependent variable predicted by the regression would be the sum, as indicated by the bars, of the regression coefficients for each significant independent variable relationship times the corresponding mean values for that variable. This effectively converts the mean value of each independent variable into proportionate units of the dependent variable and thus allows a direct visual comparison of the magnitude and direction of each effect. All formulas and procedures were as described by Seber.[32]

RESULTS

Considering data obtained from the entire course in the critical care unit (Fig 1), both NST and clinically ST patients showed increased muscle protein degradation (estimated from urinary 3MH excretion) and increased urinary urea production compared with the normal range. However, as also shown in Fig 1, the rate of urea production per gram of estimated muscle protein loss was significantly higher ($P<.0001$) by the Scheffé S method in the patients who became clinically septic.

The interpretation of this increased muscle protein degradation and increased urea production in the ST survivors is not immediately clear, since compared with the NST patients, the surviving ST patients (but not the ST MOFS deaths) received significantly higher levels of TPN-administered AAs due to their increased hyperdynamic, hypermetabolic state with increased cardiac output, oxygen consumption, and temperature (Table 2). However, in the ST patients with MOFS, excessive hyperglycemia and circulatory intolerance to large fluid volumes forced a reduction in the magnitude of TPN support (Table 2). The
